Introduction

How do species pools change over time as species are recruited or go extinct? When are ecotypes enriched or depleted? How does global and regional environmental context affect the distribution of species ecotypes (e.g. guilds) in a regional species pool?

A regional species pool is the set of species which form communities in a specific region; local communities are subsets of the regional pool. The composition of a regional species pool changes over time due to speciation, migration, extinction. Local scale processes like resource competition only affect the regional species pool if all communities are affected.

Valentine and Bambach how they presented guilds in paleobiology. Bush and Bambach presented an ecocube to describe what how marine invertebrates partition space and resources (Bambach et al., 2007; Bush and Bambach, 2011; Bush et al., 2007). Unique combinations represent what possible ecotypes are observable. The distribution of ecocube occupancy is then normally analyzed as raw counts of unique combinations or using ordination methods and the change in disparity over time is estimated (Bambach et al., 2007; Bush and Bambach, 2011; Bush et al., 2007).

One of the greatest challenges with analyzing species occurrence data is the inherent incompleteness of any sample (Foote, 2001; Foote and Sepkoski, 1999; Lloyd et al., 2011; Royle and Dorazio, 2008; Royle et al., 2014; Wang and Marshall, 2016). In the modern, only presences are certain as an absence can be caused by both the species being truly absent or the species never having been sampled (Royle and Dorazio, 2008; Royle et al., 2014). For paleontological data in the context of this study, the incomplete preservation of fossil communities combined with the incomplete sampling of what fossils there are means that the true times of origination or extinction may not be observed (Foote, 2001; Foote and Sepkoski, 1999; Wang et al., 2016; Wang and Marshall, 2016)

Smits (2015) found several systematic differences in mammal species durations associated with various species traits. Omnivorous taxa were found to have, on average, a greater duration than other dietary categories. Additionally, arboreal taxa were found to have a shorter duration than other locomotor categories.

An unresolved question from Smits (2015) is whether the greater extinction risk faced by arboreal is
28 constant over time or if there was a change in extinction risk at the Paleogene/Neogene boundary.
Specifically, the question is whether the extinction risk arboreal taxa increased in the Neogene,
30 driving the loss of arboreal taxa and average extinction risk of arboreal taxa down.

There are no observed massive cross-taxonomic turnover events in the North American record,
32 unlike the Neogene record Europe (Alroy, 1996, 2009; Alroy et al., 2000; Eronen et al., 2015; Janis,
1993).

34 The effect of climate on diversity and the diversification process has been the focus of considerable
research with many analyses favoring diversification being more biologically-mediated than
36 climate-mediated (Alroy, 1996; Alroy et al., 2000; Clyde and Gingerich, 1998; Figueirido et al.,
2012). Scale of analysis makes a big difference in interpretation of results, both temporal and
38 geographic. For example when the mammal fossil record analyzed at small temporal and geographic
scales a correlation between diversity and climate are observable (Clyde and Gingerich, 1998).
40 However, when the record is analyzed at the scale of the continent and the Cenozoic there is no
correlation with diversity and climate (Alroy et al., 2000). This results, however, does not go
42 against the idea that there may be short periods of correlation and that this correlation change or
reverse direction over time; instead this result means that there is no single direction of correlation
44 between diversity and climate (Figueirido et al., 2012). In the case of a fluctuating correlation
between diversity and climate it is hard to make the argument of an actual causal link between the
46 two without understanding the ecological differences in mammalian fauna over time; when this
analysis is based on diversity or taxonomy alone no mechanisms are possible to infer. After all,
48 taxonomy conflates many potential factors that could affect diversification into a single variable; by
separating the effects of shared common ancestry (i.e. phylogeny) from species ecology the subtle
50 differences in the diversification process can be observed (Smits, 2015).

There are many global climatic events that may have influenced the distribution of mammal
52 ecotypes regionally, if not globally (Zachos et al., 2008, 2001). PETM. The Mid-Miocene climactic
optimum. The general cooling throughout the Cenozoic and the development of ice-caps in the

Neogene. The Oligo-Miocene boundary. The transition from the Paleogene to the Neogene in North America is typically described as the “opening-up” of the landscape as partially forested environments were replaced by savannah and grasslands (Blois and Hadly, 2009; Janis, 1993; Janis et al., 2000; Strömberg, 2005).

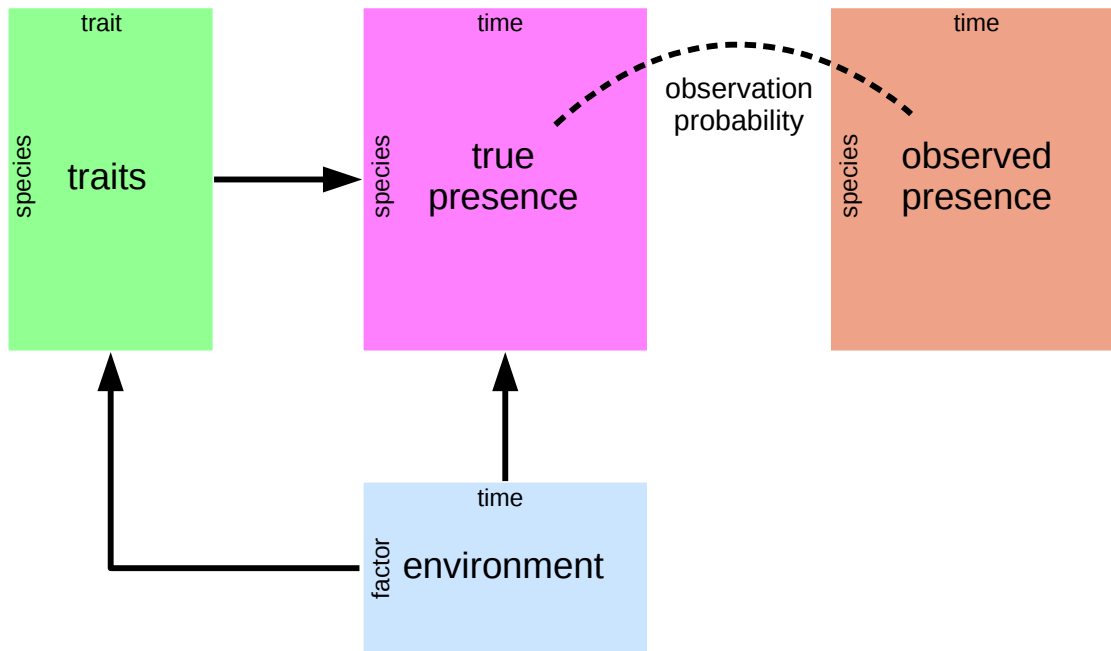

Figure 1: Conceptual diagram of the paleontological fourth corner problem. The observed presence matrix (orange) is the empirical presence/absence pattern for all species for all time points; this matrix is an incomplete observation of the “true” presence/absence pattern (purple). The estimated true presence matrix is modeled as a function of both environmental factors over time (blue) and multiple species traits (green). Additionally, the affect of environmental factors on species traits are also modeled as traits are expected to mediate the effects of a species environmental context. This diagram is based partially on material presented in Brown et al. (2014) and Warton et al. (2015).

Fourth-corner modeling an approach to explaining the patterns of either species abundance or presence/absence as a product of species traits, environmental factors, and the interaction between traits and environment CITATION. In modern ecological studies, what is being modeled is species

occurrences at localities distributed across a region CITATION. In this study, what is being modeled is the pattern of species occurrence over time for most of the Cenozoic in North America (Fig. 1). These two approaches, modern and paleontological, are different views of the same three-dimensional pattern: species at localities over time. The temporal limitations of modern ecological studies and difficulties with uneven spatial occurrences of fossils in paleontological studies means that these approaches are complimentary but reveal different patterns of how species are distributed in time and space.

The major species trait included in this study is species ecotype, defined as the combination of species dietary category (e.g. carnivore) and locomotor category (e.g. arboreal). This trait is a descriptor of a species' ecological guild, similar to the unique combinations of the ecocube used in analysis of marine invertebrates (Bambach et al., 2007; Bush and Bambach, 2011; Bush et al., 2007). Importantly, the probability of a species ecotype being present was modeled as a function of environmental factors (Fig. 1). Species mass was also included as a species trait, but primarily just to control for that effect on species occurrence.

The environmental factors included in this study include estimates of global temperature and the changing floral groups present in North America across the Cenozoic. Why are these factors important? What are the hypotheses associated with environmental context?

Materials and Methods

Taxon occurrences and species-level information

All fossil occurrence information was downloaded from the Paleobiology Database. Occurrences (PBDB) were restricted to all Mammalia sampled in North America between the Maastrichtian and Gelasian stages. Taxonomic, stratigraphic, and ecological metadata for each occurrence was included. The raw data is available for download at <http://goo.gl/2slgeU>.

This raw data was then sorted, cleaned, and manipulated programmatically prior to analysis.

Species taxonomic assignments given by the PBDB were updated for accuracy and consistency. For example, species classified in the order Artiodactyla were reclassified as Cetartiodactyla. These re-assignments follow Smits (2015) and were Janis et al. (2008, 1998) and the Encyclopedia of Life WEBSITE. Additionally, Taxa who's life habit was classified as either volant (i.e. Chiroptera) or aquatic (e.g. Cetacea) were excluded from this analysis because of both differences in fossilization potential and applicability to the study of terrestrial species pools.

The life habit and dietary categories provided through the PBDB were coarsened to increase per ecotype sample size; this coarsening follows the same procedure as Smits (2015). Additionally, life habit category was further modified to break-up the vague "ground-dwelling" category; re-classifying these species by ankle posture gives more precise information about that species' environmental context. Ground-dwelling taxa were reassigned following ? by species taxonomic context. Species ecotype is defined as the interaction between life habit and diet categories. Ecotype categories with less than 10 species having ever been that combination were excluded, yielding a total of 18 of 21 possible ecotypes.

Table 1: Species trait assignments in this study are a coarser version of the information available in the PBDB. Information was coarsened to improve per category sample size and uniformity and followed this table.

This study		PBDB categories
Diet	Carnivore	Carnivore
	Herbivore	Browser, folivore, granivore, grazer, herbivore.

Species mass information was gathered from multiple different sources where a plurality of the body size estimates are from the PBDB. Body part measurements for many species are also available through the PBDB. Just as with Smits (2015), these measurements and corresponding regression equations were used to get mass estimates for more species. Additional mass estimates and body part measurements were sourced from numerous publications and the Neogene Old World Database; see the supplementary material to Smits (2015) for details. Mass was log-transformed and then mean-centered and rescaled by dividing by two-times its standard deviation; this insures that the magnitude of effects for both continuous and discrete covariates are comparable (Gelman, 2008; Gelman and Hill, 2007).

Table 3: Regression equations used in this study for estimating body size. Equations are presented with reference to taxonomic grouping, part name, and reference.

Group	Equation	log(Measurement)	Source
General	$\log(m) = 1.827x + 1.81$	lower m1 area	Legendre (1986)
General	$\log(m) = 2.9677x - 5.6712$	mandible length	?
General	$\log(m) = 3.68x - 3.83$	skull length	?
Carnivores	$\log(m) = 2.97x + 1.681$	lower m1 length	?
Insectivores	$\log(m) = 1.628x + 1.726$	lower m1 area	?
Insectivores	$\log(m) = 1.714x + 0.886$	upper M1 area	?
Lagomorph	$\log(m) = 2.671x - 2.671$	lower toothrow area	Tomiya (2013)
Lagomorph	$\log(m) = 4.468x - 3.002$	lower m1 length	Tomiya (2013)
Marsupials	$\log(m) = 3.284x + 1.83$	upper M1 length	?
Marsupials	$\log(m) = 1.733x + 1.571$	upper M1 area	?
Rodentia	$\log(m) = 1.767x + 2.172$	lower m1 area	Legendre (1986)
Ungulates	$\log(m) = 1.516x + 3.757$	lower m1 area	?
Ungulates	$\log(m) = 3.076x + 2.366$	lower m2 length	?
Ungulates	$\log(m) = 1.518x + 2.792$	lower m2 area	?
Ungulates	$\log(m) = 3.113x - 1.374$	lower toothrow length	?

All fossil occurrences from 64 to 2 million years ago (Mya) were binned into 31 2 million year (My) bins. This temporal length was chosen because it is approximately the resolution of the North American mammal fossil record.

Environmental and temporal covariates

The group-level covariates in this study are descriptors of species' environmental context, specifically global temperature estimates and Graham's floral intervals CITATION. Global temperature across most of the Cenozoic was calculated from Mg/Ca isotope record from deep sea carbonates (Cramer et al., 2011). Mg/Ca based temperature estimates are preferable to the frequently used $\delta^{18}\text{O}$ temperature proxy (Alroy et al., 2000; Figueirido et al., 2012; Zachos et al., 2008, 2001) because Mg/Ca estimates do not conflate temperature with ice sheet volume and depth/stratification changes; this makes it preferable as an estimate of global temperature for macroevolutionary and macroecological studies (Ezard et al., 2016).

Two aspects of the Mg/Ca-based temperature curve were included in this analysis: mean and range. Both were calculated as the mean of all respective estimates for each 2 My temporal bins. Both

mean and range were then rescaled as above: subtract mean, divide by twice the standard deviation.

The other major set of environmental factors included in this study are Graham’s Cenozoic plant phases CITATION. Graham’s plant phases are holistic descriptors of the taxonomic composition of which plants were present at a given time and their relative modernity, with younger phases representing increasingly modern taxa CITATION. Graham CITATION defines four intervals from the Cretaceous to the Pliocene, though only three of these intervals are included in this analysis. Graham’s plant phases CITATION was included as a series of “dummy variables” encoding the three phases included in this analysis. This means that the first phase is synonymous with the intercept and phases

Modelling species occurrence

Two different models were used in this study: a pure-presence model and a birth-death model. Both models at their core are hidden Markov model where the latent aspect of the process has an absorbing state (Allen, 2011). The difference between these two models is if the probability of a species origination and survival are considered equal or different (Table 4). Something that is important to realize is that while there are only two state “codes” in a presence-absence matrix (i.e. 0/1), there are in fact three states in a birth-death model: never having originated, extant, and extinct. The last of these is the absorbing state, as once a species has gone extinct it cannot re-originate (Allen, 2011); this is made obvious in the transition matrices as the probability of an extinct species changing states is 0 (Table 4).

Data augmentation

All presence/absence observations are incomplete. The hidden Markov model at the core of this analysis allows for observed absences to be used meaningfully to estimate the number of unobserved species. Of specific concern in this analysis is the unknown “true” size of the dataset; how many species could have actually been observed? While many species have been observed, the natural

		State at $t + 1$		
		0_{never}	1	$0_{extinct}$
State at t	0_{never}	$1 - \theta$	θ	0
	1	0	θ	$1 - \theta$
	$0_{extinct}$	0	0	1

(a) Pure-presence

		State at $t + 1$		
		0_{never}	1	$0_{extinct}$
State at t	0_{never}	$1 - \phi$	ϕ	0
	1	0	π	$1 - \pi$
	$0_{extinct}$	0	0	1

(b) Birth-death

Table 4: Transition matrices for the pure-presence (4a) and birth-death (4b) models. Both of these models share the core machinery of discrete-time birth-death processes but make distinct assumptions about the equality of originating and surviving (Eq. 2, and 3). Note also that while there are only two state “codes” (0, 1), there are in fact three states: never having originated 0_{never} , present 1, extinct $0_{extinct}$ (Allen, 2011).

incompleteness of all observations, especially in the case of paleontological data, there are obviously

many species which were never sampled (Royle and Dorazio, 2008; Royle et al., 2007).

Let N be the total number of observed species, M be the upper limit of possible species that could have existed given a model of species presence, and N^* is the all-zero histories where $N^* = M - N$.

This approach assumes that $\hat{N} \sim \text{Binomial}(M, \psi)$ where \hat{N} is the estimated “true” number of

species and ψ is the probability that any augmented species should actually be “present.” Because M is user defined, this approach effectively gives ψ a uniform prior over N to M (Royle and

Dorazio, 2008). For this study, $M = N + \lfloor N/4 \rfloor$.

Data imputation is the process of estimating missing data for partially observed covariates (Gelman

and Hill, 2007; Rubin, 1996), this is simple in a Bayesian context because data are also parameters

(Gelman et al., 2013). Augmented species also have no known mass so a mass estimate must be

imputed for each possible species (Royle and Dorazio, 2012). This procedure assumes that mass

values for augmented species are from the same distribution as observed species. The distribution of

observed mass values is estimated as part of the model, and new mass values are then generated

from this distribution. This approach is an example of imputing data missing completely at random

(Gelman and Hill, 2007; Royle and Dorazio, 2012). Because log mass values are rescaled as a part of

this study, the body mass distribution is already known ($\mathcal{N}(0, 0.5)$); augmented species body mass

just simply drawn from this distribution.

In addition to body mass information, the augmented species need an ecotype classification. Because

Table 5: Observation parameters

Parameter	dimensions	explanation
y	$N \times T$	observed species presence/absence
z	$N \times T$	“true” species presence/absence
p	T	probability of observing a species that is present at time t
m	N	species log mass, rescaled
α_0	1	average log-odds of p
α_1	1	change in average log-odds of p per change mass
r	T	difference from α_0 associated with time t
σ	1	standard deviation of r

these species are completely unknown, they were all classified as “augmented,” an additional grouping indicating their unknown biology. This classification has no biological interpretation.

Observation process

The type of hidden Markov model used in this study has three characteristic probabilities:

probability p of observing a species given that it is present, probability ϕ of a species surviving from one time to another, and probability π of a species first appearing (Royle and Dorazio, 2008). In this formulation, the probability of a species going extinct is $1 - \pi$. For the pure-presence model $\phi = \pi$, while for the birth-death model $\phi \neq \pi$.

The probability of observing a species that is present p is modeled as a logistic regression was a time-varying intercept and species mass as a covariate. The effect of species mass on p was assumed linear and constant over time and given a prior reflecting a possible positive relationship; these assumptions are reflected in the structure of the model Equation 1. The parameters associated with this part of the model are described in Table 5.

$$\begin{aligned}
y_{i,t} &\sim \text{Bernoulli}(p_{i,t}z_{i,t}) \\
p_{i,t} &= \text{logit}^{-1}(\alpha_0 + \alpha_1 m_i + r_t) \\
r_t &\sim \mathcal{N}(0, \sigma)
\end{aligned} \tag{1}$$

Table 6: Parameters for the model of presence in the pure-presence model

Parameter	dimensions	explanation
z	$N \times T$	“true” species presence/absence
θ	$N \times T - 1$	probability of $z = 1$
a	$T - 1 \times D$	ecotype-varying intercept; mean value of log-odds of θ
m	N	species log mass, rescaled
b_1	1	effect of species mass on log-odds of θ
b_2	1	effect of species mass, squared, on log-odds of θ
U	$T \times D$	matrix of group-level covariates
γ	$U \times D$	matrix of group-level regression coefficients
Σ	$D \times D$	covariance matrix of a
Ω	$D \times D$	correlation matrix of a
τ	D	vector of standard deviations for each ecotype a_d

Pure-presence process

180 For the pure-presence model there is only a single probability dealing with the presence of a species
 θ (Table 4a). This probability was modeled as multi-level logistic regression with both species-level
182 and group-level covariates (Gelman et al., 2013; Gelman and Hill, 2007). The parameters associated
with pure-presence model are presented in Table 6 and the full sampling statement in Equation 2.

184 The species-level of the model (Eq. 2) is a logistic regression with varying-intercept that varies by
ecotype. Additionally, species mass was included as a covariate associated with two regression
186 coefficients allowing a quadratic relationship with log-odds of occurrence. This assumption is based
on the known distribution of mammal body masses where species with intermediate mass values are
188 more common than either small or large bodied species. These assumptions are also reflected in the
choice of priors for these regression coefficients.

190 The values of each ecotype’s intercept are themselves modeled as regressions using the group-level
covariates associated with environmental context. Each of these regressions has an associated
192 variance of possible values of each ecotype’s intercept (Gelman and Hill, 2007). In addition, the
covariances between ecotype intercepts, given this group-level regression, are modeled (Gelman and
194 Hill, 2007).

All parameters not modeled elsewhere were given weakly informative priors (Gelman et al., 2013)

196 CITATION STAN MANUAL STATISTICAL RETHINKING. Weakly informative means that
priors do not necessarily encode actual prior information but instead help regularize or weakly
198 constrain posterior estimates. These priors have a concentrated probability density around and near
zero; this has the effect of tempering our estimates and help prevent overfitting the model to the
200 data (Gelman et al., 2013) CITATION STAN MANUAL STATISTICAL RETHINKING.

$$\begin{aligned}
y_{i,t} &\sim \text{Bernoulli}(p_{i,t}z_{i,t}) & \alpha_0 &\sim \mathcal{N}(0, 1) \\
p_{i,t} &= \text{logit}^{-1}(\alpha_0 + \alpha_1 m_i + r_t) & \alpha_1 &\sim \mathcal{N}(1, 1) \\
r_t &\sim \mathcal{N}(0, \sigma) & \sigma &\sim \mathcal{N}^+(1) \\
z_{i,t} &\sim \text{Bernoulli}(\theta_{i,t}) & b_1 &\sim \mathcal{N}(0, 1) \\
\theta_{i,t} &= \text{logit}^{-1}(a_{t,j[i]} + b_1 m_i + b_2 m_i^2) & b_2 &\sim \mathcal{N}(-1, 1) \\
a &\sim \text{MVN}(u\gamma, \Sigma) & \gamma &\sim \mathcal{N}(0, 1) \\
\Sigma &= \text{diag}(\tau)\Omega\text{diag}(\tau) & \tau &\sim \mathcal{N}^+(1) \\
& & \Omega &\sim \text{LKJ}(2)
\end{aligned} \tag{2}$$

Birth-death process

202 In the birth-death model, $\phi \neq \pi$ and so each of these probabilities are modeled separately but in a
similar manner to how θ is modeled in the pure-presence model (Eq. 2, Table 4b). The parameters
204 associated with the birth-death presence model are presented in Table 7 and the full sampling
statement, including observation (Eq. 1), is described in Equation 3.

206 Similar to the pure-presence model, both ϕ and π are modeled as logistic regressions with
varying-intercept and one covariate associated with two parameters. The possible relationships
208 between mass and both ϕ and π are reflected in the parameterization of the model and choice of
priors (Eq. 3).

210 The intercepts of ϕ and π both vary by species ecotype and those values are themselves the product

Table 7: Parameters for the model of presence in the pure-presence model

Parameter	dimensions	explanation
z	$N \times T$	“true” species presence/absence
ϕ	$N \times T - 1$	probability of $z_{-,t} = 1 z_{-,t-1} = 0$
π	$N \times T - 1$	probability of $z_{-,t} = 1 z_{-,t-1} = 1$
a^ϕ	$T - 1 \times D$	ecotype-varying intercept; mean value of log-odds of θ
a^π	$T - 1 \times D$	ecotype-varying intercept; mean value of log-odds of θ
m	N	species log mass, rescaled
b_1^ϕ	1	effect of species mass on log-odds of ϕ
b_1^π	1	effect of species mass on log-odds of π
b_2^ϕ	1	effect of species mass, squared, on log-odds of ϕ
b_2^π	1	effect of species mass, squared, on log-odds of π
U	$T \times D$	matrix of group-level covariates
γ^ϕ	$U \times D$	matrix of group-level regression coefficients
γ^π	$U \times D$	matrix of group-level regression coefficients
Σ^ϕ	$D \times D$	covariance matrix of a^ϕ
Σ^π	$D \times D$	covariance matrix of a^π
Ω^ϕ	$D \times D$	correlation matrix of a^ϕ
Ω^π	$D \times D$	correlation matrix of a^π
τ^ϕ	D	vector of standard deviations for each ecotype a_d^ϕ
τ^π	D	vector of standard deviations for each ecotype a_d^π

of group-level regression using environmental factors as covariates (Eq. 3); this is identical to the

212 pure presence model (Eq. 2).

Posterior inference and model adequacy

214 Programs that implement joint posterior inference for the above models (Eqs. 2, 3) were
implemented in the probabilistic programming language Stan CITATION. The models used here
216 both feature latent discrete parameters in the large matrix z (Tables 5, 6, 7; Eqs. 1, 2, 3). All
methods for posterior inference implemented in Stan are derivative based which causes
218 complications for actually implementing the above models because integers do not have derivatives.
Instead of implementing a latent discrete parameterization, the posterior probabilities of all possible
220 states of the latent parameters z were estimated (i.e. marginalized).

Species durations at minimum range-through from the FAD to the LAD, but the incompleteness of

all observations means that the actual time of origination or extinction is unknown. The marginalization approach used here means that the probabilities all possible histories for a species are calculated, from the end members of the species having existed for the entire study interval and the species having only existed between the directly observed FAD and LAD to all possible intermediaries CITATION STAN MANUAL.

	Time Bin							
	1	2	3	4	5	6	7	8
Observed	0	0	0	1	0	1	1	0
Certain	?	?	?	1	1	1	1	?
Potential	0	0	0	1	1	1	1	0
Potential	0	0	1	1	1	1	1	0
Potential	0	1	1	1	1	1	1	0
Potential	1	1	1	1	1	1	1	0
Potential	0	0	0	1	1	1	1	1
Potential	0	0	1	1	1	1	1	1
Potential	0	1	1	1	1	1	1	1
Potential	1	1	1	1	1	1	1	1

Figure 2: Conceptual figure of all possible occurrence histories for an observed species. The first row represents the observed presence/absence pattern for a single species at eight time points. The second row corresponds to the known aspects of the “true” occurrence history of that species. The remaining rows correspond to all possible occurrence histories that are consistent with the observed data. The process of parameter marginalization described in the text

The combined size of the dataset and large number of parameters in both models (Eqs. 2, 3), specifically the total number of latent parameters that are the matrix z , means that stochastic approximate posterior inference is computationally very slow even using HMC. Instead, an approximate Bayesian approach was used: variational inference. A recently developed automatic variational inference algorithm called “automatic differentiation variational inference” (ADVI) is

implemented in Stan and was used here CITATION. ADVI assumes that the posterior is Gaussian but still yields a true Bayesian posterior; this assumption is similar to quadratic approximation of the likelihood function used in maximum likelihood inference CITATION. The principal limitation of assuming the joint posterior is Gaussian is that the true topology of the log-posterior isn't represented; this is a particular burden for scale parameters which are bound to be positive (e.g. standard deviation).

After fitting both models (Eqs. 2, 3) using ADVI, model adequacy and quality of fit was assessed using a series of posterior predictive checks CITATION CITATION. Because all Bayesian models are inherently generative, simulations of new data sets is “free” CITATION. By simulating many theoretical data sets using the observed covariate information the congruence between predictions made by the model and the observed empirical data can be assessed. By combining multiple posterior predictive tests of congruence between empirical and simulated values of interest, the holistic adequacy of the model can be analyzed CITATION.

An example posterior predictive check used in this study was comparing the observed average number of observations per species to a distribution of simulated averages; if the empirically observed value sits in the middle of the distribution than the model is adequate in reproducing the observed number of occurrences per species.

Posterior simulations for time series are start with the values at $t = 1$ and then just simulating forward.

Results

Comparing the fits of the pure-presence and birth-death models

Comparison of the posterior predictive performance of the pure-presence and birth-death models reveals a striking difference in quality of the models' fits to the data (Fig. 3 and 4). The birth-death model is clearly able to reproduce the observed average number of occurrence, in contrast to the

256 pure-birth model which greatly underestimates the observed average number of occurrences. The
 interpretation of these results is that the results of the birth-death model are more representative of
 258 the data than the pure-presence model, though further inspection of the posterior parameter
 estimates if generally necessary CITATION.

Figure 3: Comparison of the average observed number of occurrences per species (blue line) to the average number of occurrences from 100 posterior predictive datasets using the posterior estimates from the pure-presence model.

260 Analysis of diversity

Acknowledgements

262 I would like to thank K. Angielczyk, M. Foote, P. D. Polly, and R. Ree for helpful discussion and
 advice. This entire study would not have been possible without the Herculean effort of the
 264 many contributors to the Paleobiology Database. In particular, I would like to thank J. Alroy and
 M. Uhen for curating most of the mammal occurrences recorded in the PBDB. This is Paleobiology
 266 Database publication XXX.
