

The macroecology behind macroevolution: North American
mammal functional diversity and its relation to environmental
change

Abstract

The set of species in a region changes over time as new species enter through speciation or immigration and as species leave the system through extinction and extirpation. How a regional species pool changes over time is the product of many processes acting at multiple levels of organization. Changes in the functional composition of a regional species pool are changes that occur across all local communities drawn from that species pool. While a species' presence in a local community is due to the availability of the necessary biotic-biotic or biotic-abiotic interactions that enable coexistence, a species' presence in a regional species pool just requires that at least one local community has that set of necessary interactions. The goal of this analysis is to understand when, and possibly for what reasons, mammal ecotypes are enriched or depleted relative to their average diversity. Here, I analyze the diversity history of North American mammals ecotypes for most of the Cenozoic (the last 65 million years). This analysis frames mammal diversity in terms of both their means of interacting with the biotic and abiotic environment (i.e. functional group or ecotype) as well as their regional and global environmental context. Using two hierarchical Bayesian hidden Markov models of diversity, I find that changes to mammal diversity are driven more by the influx of new species than by selective extinction. I also find that the only ecotypes which experience a near constant increase in diversity over time are digitigrade and unguligrade herbivores, while arboreal ecotypes become increasingly rare and in many cases disappear entirely from the species pool over the Cenozoic. Additionally, I find that global temperature is only associated with the origination of some mammal ecotypes but, in almost all cases, does not affect the extinction of mammal ecotypes.

Introduction

Changes to species diversity are the result of evolutionary and ecological processes acting in concert and continually over time. Local communities are shaped by dispersal and local ecological processes such as resource competition and predator-prey relationships. The constituent species of these communities are drawn from a regional species pool, or the set of all species that are present in at least one community within a region (Harrison and Cornell, 2008; Mittelbach and Schemske, 2015; Urban et al., 2008). Species dispersal from the regional species pool to the local communities is a

sorting process shaped by biotic and abiotic environmental filters which are mediated by those
30 species' traits (Cottenie, 2005; Elith and Leathwick, 2009; Harrison and Cornell, 2008; Loeuille and
Leibold, 2008; Shipley et al., 2006; Urban et al., 2008). Regional species pools are shaped by
32 speciation, extinction, migration, and extirpation. The gain or loss of regional diversity is the result
of macroevolutionary dynamics which, in turn, shape the downstream macroecological dynamics of
34 the regional species pool and its constituent local communities (Harrison and Cornell, 2008;
Mittelbach and Schemske, 2015; Urban et al., 2008). In turn, the distribution of species within
36 regional species pool represents the expected distribution of local communities under a purely
diffusive process of community assembly as would be expected neutral theory of biodiversity
38 CITATION.

Fundamentally, all species respond differently to climate and environmental change (Blois and
40 Hadly, 2009). Those species with similar ecological roles within a regional species pool can be
described as belonging to a guild or functional group (Bambach, 1977; Brown and Maurer, 1989;
42 Simberloff and Dayan, 1991; Valentine, 1969; Wilson, 1999). Species within the same functional
group are expected to have more similar macroecological dynamics to each other than to species of
44 a different functional group. By focusing on the relative diversity of functional groups, changes to
diversity are interpretable as changes to the set of ways species within a species pool could interact
46 with the biotic and abiotic environment.

A key question when comparing communities or regional species pools based on their functional
48 composition is whether specific functional groups are enriched or depleted and why; what are the
processes that led to a species pool having the functional composition it does (Blois and Hadly,
50 2009; Brown and Maurer, 1989; McGill et al., 2006; Smith et al., 2008; Weber et al., 2017)?

Comparisons of contemporaneous regional species pools can only determine if a functional group is
52 enriched or depleted in one species pool relative to the other species pools CITATION. These types
of comparison do not take into account if a functional group is enriched or depleted relative to its
54 diversity over time (Blois and Hadly, 2009). While a species pool may be depleted of a functional
group relative to other contemporaneous species pools, that same functional group may be actually
56 be enriched in that species pool relative to its historical diversity. Because the processes which

shape regional species pool diversity (e.g. origination, extinction) operate on much longer time scales than is possible for studies of the Recent, paleontological data provides a unique opportunity to observe and estimate the changes to functional diversity and how species functional traits and environmental context can shape the enrichment or depletion of functional groups within a regional species pool (Blois and Hadly, 2009; Smith et al., 2008). Being able to identify if the diversity of a functional group is depleted relative to their long term average diversity in the species pool is particularly useful in conservation settings; species in depleted groups are most likely more at risk of extinction than species in enriched groups, even if those enriched groups are relatively rare when compared to the functional composition of other contemporaneous species pools.

The paleontological record of North American mammals for the Cenozoic (\sim 66 million years ago to the present) provides one of the best opportunities for understanding how regional species pool functional diversity changes over time. The North American mammal record is a relatively complete temporal sequence for the entire Cenozoic which is primarily, but not exclusively, based on fossil localities from the Western Interior of North America (Alroy, 1996, 2009; Alroy et al., 2000). Additionally, mammal fossils preserve a lot of important physiological information, such as teeth, so that functional traits like the dietary/trophic category of species are easy to estimate (Eronen et al., 2010; Polly et al., 2011, 2015).

The goals of this study are to understand when are unique functional groups enriched or depleted in the North American mammal regional species pool and to estimate the relationship between these changes to regional ecotypic diversity and changes to their environmental context. My contribution is to develop a joint model of observation, origination, survival, as well as the effects of species traits and environmental factors on these processes.

Background

The history of standing diversity for all mammals along with that some individual clades of North American mammals for the Cenozoic has been the focus of considerable study (Alroy, 1996, 2009; Alroy et al., 2000; Badgley and Finarelli, 2013; Blois and Hadly, 2009; Figueirido et al., 2012;

Fraser et al., 2015; Janis, 1993; Janis and Wilhelm, 1993; Pires et al., 2015; Quental and Marshall, 84 2013; Silvestro et al., 2015; Slater, 2015; Smits, 2015). Previous approaches to understanding mammal diversity, both in North America and elsewhere, fall into a number of overlapping 86 categories: total diversity (Alroy, 1996; Alroy et al., 2000; Figueirido et al., 2012; Liow et al., 2008), with/between guild comparisons (Janis et al., 2004; Janis, 2008; Janis et al., 2000; Janis and 88 Wilhelm, 1993; Jernvall and Fortelius, 2004; Pires et al., 2015), within/between clade comparisons (Cantalapiedra et al., 2017; Fraser et al., 2015; Quental and Marshall, 2013; Silvestro et al., 2015; 90 Slater, 2015), and estimating the impact of environmental process on total diversity (Alroy et al., 2000; Badgley and Finarelli, 2013; Badgley et al., 2017; Blois and Hadly, 2009; Eronen et al., 2015; 92 Fraser et al., 2015; Janis, 1993; Janis and Wilhelm, 1993). Each of these studies provide a limited perspective on the macroevolutionary and macroecological processes shaping diversity and 94 diversification. Integration across perspectives is necessary for producing a holistic and internally consistent picture of how the North American mammal species pool has changed through time. One 96 of the goals of this study is to present a framework for approaching hypotheses about diversity and diversification through multiple lenses simultaneously through a joint model so that any inferences 98 are better constrained and the relative importance of species' ecological function, taxonomic affinities, and environmental context may be better elucidated.

100 The narrative of the diversification of North American mammals over the Cenozoic is one of gradual change. There is little convincing evidence that there have been any sudden 102 cross-functional or cross-taxonomic group turnover events in mammal diversity at any point in the Cenozoic record of North America (Alroy, 1996, 2009; Alroy et al., 2000; Eronen et al., 2015; Janis, 104 1993). Instead of being concentrated at specific time intervals, species turnover has been found to be distributed through time. It is then expected then that, for this analysis, turnover events or 106 periods of rapid diversification or depletion should not occur simultaneously for all functional groups under study. Additionally, changes to mammal diversification seem to be primarily driven by 108 changes to origination rate and not to extinction (Alroy, 1996, 2009; Alroy et al., 2000). An unresolved aspect of the general history of mammal diversification is whether that diversity is 110 limited or self-regulating; namely, to what extent is mammal diversification diversity-dependent

(Alroy, 2009; Harmon and Harrison, 2015; Rabosky, 2013; Rabosky and Hurlbert, 2015). Similarity,
112 this question can also be asked of specific functional groups (Jernvall and Fortelius, 2004; Quental
and Marshall, 2013; Silvestro et al., 2015; Van Valkenburgh, 1999).

114 Within the overall narrative of mammal diversity, the histories of some functional and taxonomic
groups are better understood than others. These groups include ungulate herbivores and Neogene
116 carnivores which have particularly good fossil records and have been the focus of previous analyses.

The diversity history of ungulate herbivores has been characterized by more recently originating
118 taxa having longer legs, higher crowned teeth, and a shift from graze-dominated to
browse-dominated diets than their earlier originating counterparts (Cantalapiedra et al., 2017;
120 Fraser et al., 2015; Janis et al., 2004; Janis, 1993, 2008; Janis et al., 2000). The mechanisms which
drive this pattern are theorized to be some combination of tectonic activity driving environmental
122 change such as the drying of the western interior of North America due mountain building and
global temperature and environmental change such as the formation of polar icecaps (Badgley et al.,
124 2017; Blois and Hadly, 2009; Eronen et al., 2015; Janis, 2008).

In contrast, the origination of modern cursorial carnivore forms was not until later in the Cenozoic;
126 this is not to say that carnivore diversity only grew in the late Cenozoic, but that those forms were
late entrants (Janis and Wilhelm, 1993). Instead, the diversity history of carnivores is reflective of
128 density-dependence or some other form of self-regulation (Silvestro et al., 2015; Slater, 2015; Van
Valkenburgh, 1999). Specifically, it has been proposed that different canid clades have replaced each
130 other as the dominate members of their functional group within the species pool (Silvestro et al.,
2015; Van Valkenburgh, 1999). It is then expected that, for this analysis, the diversity of digitigrade
132 and plantigrade carnivores (i.e. the “carnivore” guild of Van Valkenburgh (1999)) should be
relatively constant for the Cenozoic or at least have plateaued by the Neogene.

134 In a relevant study, Smits (2015) found that functional traits such as a species dietary or locomotor
category structure differences in mammal extinction risk. In particular, arboreal taxa were found to
136 have a shorter duration on average than species from other locomotor categories (Smits, 2015). Two
possible scenarios that could yield this pattern were proposed: the extinction risk faced by arboreal

138 species is constant and high for the entire Cenozoic or the Paleogene and Neogene represent
139 different regimes and extinction risk increased in the Neogene, thus driving up the Cenozoic average
140 extinction risk. These two possible explanations have clear and testable predictions with respect to
141 the diversity history of arboreal taxa: 1) if arboreal taxa always have an elevated extinction risk
142 when compared to other taxa, then the diversity history of arboreal taxa is expected to be constant
143 with time, albeit possibly at low diversity; and 2) if the Paleogene and Neogene represent difference
144 selective regimes with the former being associated with lower extinction risk than the latter, then
145 the diversity history of arboreal taxa are expected to be present in the Paleogene but depleted or
146 absent from the species pool during the Neogene.

There is a lack of consensus as to the effect of species body size on mammal diversity and aspects of
148 the diversification processes, specifically extinction (Liow et al., 2008, 2009; Smits, 2015; Tomiya,
149 2013). Species body size is frequently framed as an important biological descriptor because of its
150 correlation with other important and relevant ecological traits such as metabolic rate and home
151 range size (Brown, 1995). It is also relatively easy to estimate for extinct species using proxy
152 measures and regression equations, as was done in this study (see below). However, body size is
153 normally analyzed without simultaneous reference to other relevant species traits (Huang et al.,
154 2017; Liow et al., 2008; Raia et al., 2012; Smith et al., 2004), but see (Smits, 2015); this combined
155 with the high amount of correlation between life history traits and body size limits process-based
156 inference, because the actual causal mechanisms underlying an observed pattern are obscured or
157 missing.

158 The climate history of the Cenozoic can be broadly described as a gradual cooling trend, with polar
159 ice-caps forming in the Neogene (Cramer et al., 2011; Zachos et al., 2008, 2001). There are of course
160 exceptions to this pattern such as the Eocene climatic optimum, the mid-Miocene climatic
161 optimum, and the sudden drop in temperature at the Eocene/Oligocene boundary (Zachos et al.,
162 2008, 2001). In terms of the North American biotic environment, the Cenozoic is additionally
163 characterized by major transition from having closed, partially forested biomes being common in
164 the Paleogene to the landscape being dominated by savannah and grasslands biomes by the
Neogene (Blois and Hadly, 2009; Janis, 1993; Janis et al., 2000; Strömberg, 2005). Additionally, the

¹⁶⁶ landscape structure and topology of North America changed substantially over the Cenozoic with
¹⁶⁷ mountain uplift and other tectonic actives in Western North America (Badgley and Finarelli, 2013;
¹⁶⁸ Blois and Hadly, 2009; Eronen et al., 2015; Janis, 2008). This type of geological activity affects
¹⁶⁹ both local climates as well as continental weather patterns while also mobilizing increased grit into
¹⁷⁰ the environment, something which may be responsible for increasing trend of hyposodony (high
¹⁷¹ crowned teeth) among ungulate and rodent herbivores (Damuth and Janis, 2011; Janis, 1993;
¹⁷² Jardine et al., 2012; Jernvall and Fortelius, 2002) Badgley CITATION.

The Eocene-Oligocene transition has been observed to be associated with extinction of many
¹⁷⁴ ungulate taxa (Janis, 2008). This boundary also marks the transition from the Paleogene to the
Neogene and from herbivores being browsing dominated to grazing dominated, though not
¹⁷⁶ concurrently (Janis, 1993; Strömberg, 2005). Additionally, the Paleogene-Neogene boundary marks
the approximate start of Antarctic ice sheets, which were previously absent (Zachos et al., 2008).
¹⁷⁸ There is an observed stability in estimates of global temperature from the E/O transition till the
end of the Miocene called the Mid-Miocene climatic optimum (Zachos et al., 2008, 2001). The
¹⁸⁰ Mid-Miocene climatic optimum is bookended by periods of temperature decline. We would then
expect that, for the Miocene, turnover and other diversification events would most likely be due to
¹⁸² biological interactions or immigration and not biotic-abiotic interactions because of the constancy
of the climate, and that those groups that are driven primarily by environmental factors, the
¹⁸⁴ Miocene would be a period of marked by an absence of major changes to diversity or the
diversification process.

¹⁸⁶ The effect of climate on mammal diversity and its accompanying diversification process has been
the focus of considerable research with a slight consensus favoring mammal diversification being
¹⁸⁸ more biologically-mediated than climate-mediated when considering the entire Cenozoic (Alroy
et al., 2000; Clyde and Gingerich, 1998; Figueirido et al., 2012). However, differences in temporal
¹⁹⁰ and geographic scale seem to underly the contrast between these two perspectives. For example
when the mammal fossil record analyzed at small temporal and geographic scales a correlation
¹⁹² between diversity and climate is observable (Clyde and Gingerich, 1998). However, when the record
is analyzed at the scale of the continent and most of the Cenozoic this correlation disappears (Alroy

¹⁹⁴ et al., 2000). This result, however, does not go against the idea that there may be short periods of correlation between diversity and climate and that this relationship can change or even reverse
¹⁹⁶ direction over time; this type result means that there is no single direction or longterm correlation between diversity and climate (Figueirido et al., 2012).

¹⁹⁸ In the case of a fluctuating correlation between diversity and climate it is hard to make the argument for an actual causal link between the two without modeling the underlying ecological
²⁰⁰ differences between species; after all, species respond differently based on their individual ecologies (Blois and Hadly, 2009). When analysis is based on diversity or taxonomy alone no mechanisms are
²⁰² possible to infer. Taxonomy, like body size, stands in for many important species traits to the point that mechanistic or process based inference is impossible. While emergent patterns might
²⁰⁴ correspond to taxonomic grouping, this itself is an emergent phenomenon. Instead, by framing hypotheses in terms of species traits and their environmental context, these emergent phenomena
²⁰⁶ can be observed and analyzed rather than assumed.

Foreground

²⁰⁸ The fourth-corner problem is conceptual and statistical framework to explaining the patterns of either species abundance or presence/absence in a community as a product of species traits,
²¹⁰ environmental factors, and the interaction between traits and environment (Brown et al., 2014;
Jamil et al., 2013; Pollock et al., 2012; Warton et al., 2015); effectively uniting climate-based species
²¹² distribution modeling (SDMs) with trait-based community assembly models (CATS, MaxEnt). The fourth-corner problem is normally phrased in modern ecological studies as understanding how traits
²¹⁴ and environment interact to predict the occurrence of species at localities distributed across a region (Jamil et al., 2013; Pollock et al., 2012).

²¹⁶ This conceptual framework can be extended to include time when considering occurrence as a three-dimensional: species at localities in space over time. This extension changes the goal of
²¹⁸ predicting just occurrence to one of predicting species gain and loss at localities. However, the temporal limitations of modern ecological studies limit studying species over their entire durations,

220 where speciation and extinction govern the occurrence of species. By considering the patterns of
fossil occurrences in the geological record the macroevolutionary processes governing species'
222 (macro)ecology can be better understood. One limitation of the fossil record, however, is a lack of
spatial resolution for most taxonomic groups and periods of time. As such, paleontological data
224 "looks" at a different side of the three-dimensional occurrence matrix of the extended fourth-corner
problem than modern ecological data.

226 In this study, the fourth-corner problem is phrased as understanding how mammal functional
groups respond to environmental change in order to predict the origination and survival of species
228 over time (Fig. 1). Additionally, I also consider the incompleteness of the fossil record and the static
effect of other species descriptors not related to functional group on origination and survival.

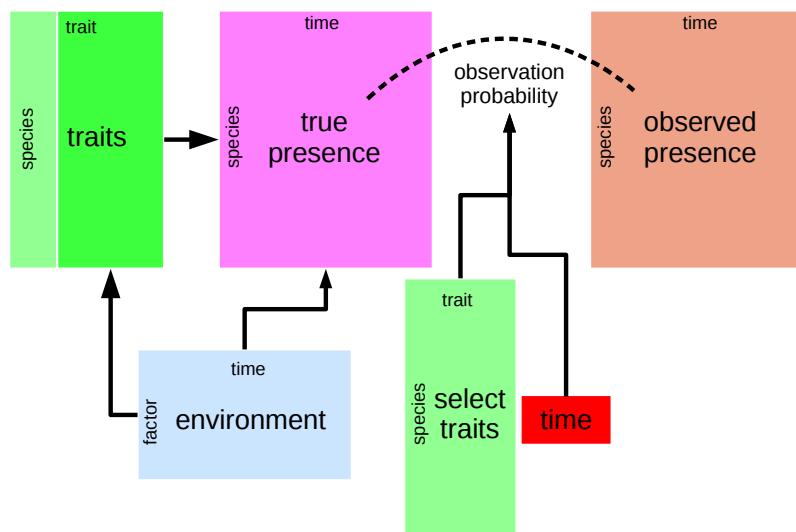

Figure 1: Conceptual diagram of the analysis at the center of this study. The observed presence matrix (orange) is the empirical presence/absence pattern for all species for all time points; this matrix is an incomplete observation of the "true" presence/absence pattern (purple). This observation process is modeled as a function of both time (red) and a selection of species traits (green). The estimated true presence matrix is modeled as a function of both environmental factors over time (blue) and multiple species traits (green). Additionally, the effects of environmental factors on some of those species traits are also modeled, as traits are expected to mediate the effects of a species environmental context. This diagram is based partially on material presented in Brown et al. (2014) and Warton et al. (2015).

230 My approach to delimiting and assigning mammal functional groups is inspired on the ecocube
heuristic used to classify marine invertebrate species by three functional traits (Bambach et al.,
232 2007; Bush and Bambach, 2011; Bush et al., 2007; Bush and Novack-Gottshall, 2012;
Novack-Gottshall, 2007; Villéger et al., 2011). In this study, the two functional traits used to define
234 a species' functional group are dietary (e.g. herbivore, carnivore, etc.) and locomotor category (e.g.
arboreal, unguligrade, etc.). Species body mass was also included as a species trait in this analysis,
236 but not as a trait for defining a functional group; instead, its inclusion is principally to control for
differences in species dynamics that driven by mass and not functional group.

238 The environmental covariates included in this study are estimates of global temperature as well as
which of three high-level North American plant taxonomic phases corresponds to that temporal
240 unit (Cramer et al., 2011; Graham, 2011). These covariates were chosen because they provide a
characterizations of the environmental context of the entire North American regional species pool
242 for most of the Cenozoic. Importantly, the effects of a species functional group on diversity are
themselves modeled as functions of environmental factors (Fig. 1) allowing for inference as to how a
244 species ecology can mediate selective pressures do to its environmental context.

All observations, paleontological or modern, are made with uncertainty. With presence/absence
246 data this uncertainty comes from not knowing if an absence is a “true” absence or just a failure to
observe (Foote, 2001; Foote and Sepkoski, 1999; Lloyd et al., 2011; Royle and Dorazio, 2008; Royle
248 et al., 2005; Wang and Marshall, 2016). For paleontological data, the incomplete preservation and
sampling of species means that the true times of origination or extinction may not be observed
250 (Foote, 2001; Foote and Sepkoski, 1999; Wang et al., 2016; Wang and Marshall, 2016). The model
used in this analysis is a translation of the conceptual framework described above (Fig. 1) into a
252 statistical model in order to estimate the relative diversity of mammal functional groups over time
and how those functional groups respond to changes to environmental context while taking into
254 account the fundamental incompleteness of the fossil record.

Ultimately, the goals of this analysis are to understand when are different functional groups
256 enriched or depleted in the North American mammal regional species pool and how these changes

in functional diversity are related to changes in species' environmental context. In the analysis
258 performed here, I consider multiple covariates which describe a species' macroecology and
environmental context. In order to analyze this complex, multi-level question and accompanying
260 highly-structured data set, I developed a hierachal Bayesian model combing the fourth-corner
modeling approach with a model of an observation-occurrence or observation-originatation-extinction
262 process.

Materials and Methods

264 Taxon occurrences and species-level information

All fossil occurrence information used in this analysis was downloaded from the Paleobiology
266 Database (PBDB). The initial download restricted occurrences to Mammalia observed in North
America between the Maastrichtian (72-66 Mya) and Gelasian (2.58-1.8 Mya) stages (Cohen et al.,
268 2015). Taxonomic, stratigraphic, and ecological metadata for each occurrence and species was also
downloaded. A new download for a raw, unfiltered PBDB datafile following the same criterion used
270 here is available at <http://goo.gl/2s1geU>. The raw datafile used as a part of this study, along
with all code for filtering and manipulating this download is available at
272 <http://github.com/psmits/copings>.

After being downloaded, the raw occurrence data was then sorted, cleaned, and manipulated
274 programmatically before analysis. Occurrences were restricted to those occurring between 64 and 2
million years ago (Mya); this age restriction was to insure that observation time series lines up with
276 the temperature time series (Cramer et al., 2011). All taxa whose life habit was classified as either
volant (i.e. Chiroptera) or aquatic (e.g. Cetacea) were excluded from this analysis because of their
278 lack of direct applicability to the study of terrestrial species pools.

Many species taxonomic assignments as present in the raw PBDB data were updated for accuracy
280 and consistency. Species present in the PBDB have some taxonomic information, including possible
Family and Order assignments. In order to increase consistency between species and reflect more

recent taxonomic assignments, each species taxonomic assignments updated as follows: 1) species family and order assignemnts as present in the Encyclopedia of life (<http://eol.org>) was downloaded using the *taxize* package for R; 2) for species not present in the EoL or not assigned order, their taxonomic inforation was further updated based on whatever family information was recorded in the PBDB or EoL; 3) for species still missing order assignemnts, their genus information was used to assign either an order or family, which was then used to assign an order.

This procedure is similar to that used in Smits (2015) and is detailed in the code repository associated with this study.

Species functional group is defined as the combination of locomotor and diet categories; the goal is to classify species based on the manner with which they interact with their environment. Mammal species records in the PBDB have life habit (i.e. locomotor category) and dietary category assignments. In order to simplify interpretation, analysis, and per-functional group sample size these classifications were coarsened in a similar manner to Smits (2015) (Table 1). Ground dwelling species locomotor categories were then reassigned based on the ankle posture associated with their taxonomic group, as described in Table 2 (Carrano, 1999). Ankle posture was assumed uniform for all species within a taxonomic group except for those species assigned a non-ground dwelling locomotor category in the PBDB, which retained their non-ground dwelling assignment. All species for which it was possible to assign a locomotor category had one assigned, including species for which post-cranaia are unknown but for which a taxonomic grouping is known. Ground dwelling species which were unable to be reassigned based on ankle posture were excluded from analysis.

Finally, ecotype categories with less than 10 total species were excluded, yielding a total of 18 observed ecotypes out of a possible 24.

Table 2: Ankle posture assignment as based on taxonomy. Assignments are based on (Carrano, 1999). Taxonomic groups are presented alphabetically and without reference for their relatedness.

304

Estimates of species mass used in this study were sourced from multiple databases and papers,
306 especially those focusing on similar macroevolutionary or macroecological questions (Brook and
Bowman, 2004; Freudenthal and Martín-Suárez, 2013; McKenna, 2011; Raia et al., 2012; Smith
308 et al., 2004; Tomiya, 2013); this is similar to Smits (2015). When a species' mass was not available,
proxy measures were used to estimate their mass. For example, given a measurement of a mammal
310 tooth size, it is possible and routine to estimate its mass given some regression equation. The
PBDB has one or more body part measures for many species. These were used as body size proxies
312 for many species, as was the case in Smits (2015). Mass was log-transformed and then rescaled by
first subtracting mean log-mass from all mass estimates, then dividing by two-times its standard
314 deviation; this insures that the magnitude of effects for both continuous and discrete covariates are

Table 1: Species trait assignments in this study are a coarser version of the information available in the PBDB. Information was coarsened to improve per category sample size.

Ungulates	$\log(m) = 1.518x + 2.792$	lower m2 area	Mendoza et al. (2006)
Ungulates	$\log(m) = 3.113x - 1.374$	lower toothrow length	Mendoza et al. (2006)

- 318 All fossil occurrences from 64 to 2 million years ago (Mya) were binned into the 19 North American Land Mammal Ages (NALMA) covered by this interval CITATION. The choice of binning by
 320 NALMA reflects the belief that these represent distinct communities or periods of mammal evolution, something that is central to this study. Additionally, because of the inherently discrete
 322 nature of the fossil record it can be hard to re-bin fossils by temporal interval because of the

Table 4: Definitions of the start and stop times of the three plant phases used this study as defined by Graham (2011).

Plant phase	Phase code	Start	Stop
Paleocene-Eocene	Pa-Eo	66	50
Eocene-Miocene	Eo-Mi	50	16
Miocene-Pleistocene	Mi-Pl	16	2

inherent uncertainty in their ages CITATION.

324 Environmental and temporal covariates

The environmental covariates used in this study are collectively referred to as group-level covariates
 326 because they predict the response of a “group” of individual-level observations (i.e. species
 occurrences of an ecotype). Additionally, these covariates are defined for temporal bins and not the
 328 species themselves; as such they predict the individual parts of each species occurrence history. The
 group-level covariates in this study are two global temperature estimates and the Cenozoic “plant
 330 phases” defined by Graham (2011).

Global temperature across most of the Cenozoic was calculated from Mg/Ca isotope record from
 332 deep sea carbonates (Cramer et al., 2011). Mg/Ca based temperature estimates are preferable to
 the frequently used $\delta^{18}\text{O}$ temperature proxy (Alroy et al., 2000; Figueirido et al., 2012; Zachos
 334 et al., 2008, 2001) because Mg/Ca estimates do not conflate temperature with ice sheet volume and
 depth/stratification changes. The former is particularly important to this analysis as the current
 336 polar ice-caps appeared and grew during the second half of the Cenozoic. These properties make
 Mg/Ca based temperature estimates preferable for macroevolutionary and macroecological studies
 338 (Ezard et al., 2016). Temperature was calculated as the mean of all respective estimates for each of
 the NALMA units. The distributions of temperature was then rescaled by subtracting its mean
 340 from all values and then dividing by twice its standard deviation.

The second set of environmental factors included in this study are the Cenozoic plant phases
 342 defined in Graham (2011). Graham’s plant phases are holistic descriptors of the taxonomic
 composition of 12 ecosystem types, which plants are present at a given time, and the relative

		State at $t + 1$		
		0_{never}	1	$0_{extinct}$
State at t	0_{never}	$1 - \pi$	π	0
	1	0	ϕ	$1 - \phi$
	$0_{extinct}$	0	0	1

Table 5: Transition matrix for the birth-death model (Eq. 1). Note that while there are only two state “codes” (0, 1), there are in fact three states: never having originated 0_{never} , present 1, extinct $0_{extinct}$ (Allen, 2011). The two modeled transition probabilities are origination π and survival ϕ .

344 modernity of those plant groups with younger phases representing increasingly modern taxa
 (Graham, 2011). Graham (2011) defines four intervals from the Cretaceous to the Pliocene, though
 346 only three of these intervals take place during the time frame being analyzed. Graham’s plant
 phases was included as a series of “dummy variables” encoding the three phases included in this
 348 analysis (Gelman and Hill, 2007); this means that the Miocene-Pleistocene phase is synonymous
 with the intercept and other phases are defined by their differences from this baseline. The
 350 temporal boundaries of these plant phases, their durations, and abbreviations are defined in Table 4.

Modelling species occurrence

352 At the core of the model used in this study is hidden Markov process where the latent process has
 an absorbing state; also referred to as a discrete-time birth-death model (Allen, 2011) or a
 354 capture-mark-recapture model CITATION. While there are only two state “codes” in a
 presence-absence matrix (i.e. 0/1), there are in fact three states in a birth-death model: not having
 356 originated yet, extant, and extinct. The last of these is the absorbing state, as once a species has
 gone extinct it cannot re-originate (Allen, 2011). Thus, in the transition matrices the probability of
 358 an extinct species changing states is 0 (Table 5). See below for parameter explanations (Tables 6, 7,
 and 8).

360 **Basic model**

I will begin defining the model used in this study by focusing on the basic machinery of the hidden
 362 Markov process at the model’s core. This basic model is similar to the Jolly-Seber

Table 6: Parameters associated with the hidden Markov Model at core of this model (Eq. 1). N is the number of species tracked in this study, and T is the number of time units (NALMAs) covered by this study.

Parameter	dimensions	explanation
y	$N \times T$	observed species presence/absence
z	$N \times T$	“true” species presence/absence
p	$N \times T$	probability of observing a species at time t if it is present
ϕ	$N \times T$	probability of species originating from time t to $t + 1$ if it is not present
π	$N \times (T - 1)$	probability of species surviving at time t , given that it is already originated

capture-mark-recapture model CITATION which has three characteristic probabilities: probability
 364 p of observing a species given that it is present, probability π of a species surviving from one time
 to another, and probability ϕ of a species first appearing (Royle and Dorazio, 2008) (Table 6). In
 366 this formulation, the probability of a species becoming extinct is $1 - \pi$. The inclusion of species and
 temporal information means that all three of these probabilities are defined for every species at
 368 every time point (Table 6); how this is accomplished is described below. Importantly, only
 origination can occur during the first time step as nothing is already present to survive.

$$\begin{aligned}
 y_{i,t} &\sim \text{Bernoulli}(p_{i,t} z_{i,t}) \\
 z_{i,1} &\sim \text{Bernoulli}(\phi_{i,1}) \\
 z_{i,t} &\sim \text{Bernoulli} \left(z_{i,t-1} \pi_{i,t} + \sum_{x=1}^t (1 - z_{i,x}) \phi_{i,t} \right)
 \end{aligned} \tag{1}$$

370 The parameters associated with Equation 1 are described in Table 6; this formulation is identical to
 that described in Royle and Dorazio (2008). The product term that appears when calculating
 372 values of z not at $t = 1$ ensures that once a species goes extinct it does not re-originate. The basic
 model described here (Eq. 1) does not include the additional, necessary prior information which is
 374 described below.

Expanding on the basics

376 Expanding on the basic model involves modeling the observation, origination and survival
 probability as independent multi-level logistic regressions. Origination and survival probabilities

378 share the same covariates and model structure, but observation probability is modeled as a function
of a smaller selection of covariates.

380 The probability of observing a species given that it is present p is modeled as a logistic regression
with a time-varying intercept with an additional zero-centered varying effect for species' functional
382 group, respectively. The effect of species mass was also included through a slope term β^p .

The log-odds of a species originating (logit π) or surviving (logit ϕ) are modeled independently but
384 take the same form: a regression with an intercept that varies by both time and functional group,
an additional taxonomic order varying-intercept term, and the slope term for species mass.

386 Importantly, the time and functional group varying-intercept is itself modeled such that the
intercept for each functional group is a time series with group-level covariates (described below).

388 The expanded model incorporating these regression models is written as

$$\begin{aligned} y_{i,t} &\sim \text{Bernoulli}(p_{i,t} z_{i,t}) \\ p_{i,t} &= \text{logit}^{-1}(u_t + e_{j[i]} + \beta^p m_i) \\ z_{i,1} &\sim \text{Bernoulli}(\phi_{i,1}) \\ z_{i,t} &\sim \text{Bernoulli}\left(z_{i,t-1} \pi_{i,t} + \sum_{x=1}^t (1 - z_{i,x}) \phi_{i,t}\right) \\ \phi_{i,t} &= \text{logit}^{-1}(f_{j[i],t}^\phi + o_{k[i]}^\phi + \beta^\phi m_i). \\ \pi_{i,t} &= \text{logit}^{-1}(f_{j[i],t}^\pi + o_{k[i]}^\pi + \beta^\pi m_i) \end{aligned} \tag{2}$$

How the priors for the varying-effects and coefficients in this expanded model are described below
390 along with the complete model.

Complete model

392 The expanded model (Eq. 2) is still incomplete as it is missing the group-level covariates of interest
such as global temperature, and it is missing all of the necessary priors.

394 Here I describe how the effects of mammal functional group on origination and survival are

Table 7: Parameters for the first expansions

Parameter	dimensions	explanation
u	T	time-varying intercept
e	J	effect of functional group on observation
f^ϕ	$J \times T - 1$	intercept of log-odds ϕ , varies by time and functional group
f^π	$J \times T$	intercept of log-odds π , varies by time and functional group
o^ϕ	K	effect of species' order on log-odds of ϕ
o^π	K	effect of species' order on log-odds of π
β^ϕ	1	effect of species' mass on log-odds of ϕ
β^π	1	effect of species' mass on log-odds of π

modeled. f^ϕ and f^π are modeled as the responses from a multivariate normal distribution, where

396 each functional group's time series is modeled as a regression. The time-series structure of these
 regressions is represented as a random-walk prior for the varying intercept of the group-level
 398 regressions. The effects of these group-level covariates on origination and survival are included for
 each functional group as a vector regression coefficients. The expansion to include this group-level
 400 regression is described in Equation 3, the parameters of which are described in Table 8.

$$\begin{aligned}
 f^\phi &\sim \text{MVN}(\mu^\phi, \Sigma^\phi) \\
 f^\pi &\sim \text{MVN}(\mu^\pi, \Sigma^\pi) \\
 \mu_{j,t}^\phi &= \alpha_{j,t}^\phi + U * \gamma_j^\phi \\
 \mu_{j,t}^\pi &= \alpha_{j,t}^\pi + U * \gamma_j^\pi \\
 \alpha_{j,t}^\phi &\sim \begin{cases} \mathcal{N}(0, 1) & \text{if } t = 1 \\ \mathcal{N}(\alpha_{j,t-1}^\phi, \sigma_j^\phi) & \text{if } t > 1 \end{cases} \\
 \alpha_{j,t}^\pi &\sim \begin{cases} \mathcal{N}(0, 1) & \text{if } t = 1 \\ \mathcal{N}(\alpha_{j,t-1}^\pi, \sigma_j^\pi) & \text{if } t > 1 \end{cases}
 \end{aligned} \tag{3}$$

In hierarchical models like the one described here (Eq. 2, 3) it can be hard to distinguish between

402 the likelihood and prior as data can enter the model through many different parameters CITATION.
 For example, in Equation 2 the model of z can be considered a prior and statements in Equation 3

Table 8: Parameters for the group-level regressions. J is the number of functional groups, and D is the number of group-level covariates.

Parameter	dimensions	explanation
μ^ϕ	$J \times T$	time-series of the mean log-odds of ϕ for each functional group
μ^π	$J \times T$	time-series of the mean log-odds of π for each functional group
Σ^ϕ	$J \times J$	covariance matrix between functional groups for ϕ
Σ^π	$J \times J$	covariance matrix between functional groups for ϕ
α^ϕ	$J \times T$	time-varying intercept of μ^ϕ
α^π	$J \times T$	time-varying intercept of μ^π
σ^ϕ	J	scale of random-walk prior for α^ϕ
σ^π	J	scale of random-walk prior for α^π
γ^ϕ	D	group-level regression coefficients for μ^ϕ
γ^π	D	group-level regression coefficients for μ^π

404 can be considered priors for the parameters which predict ϕ and π . The remaining priors necessary
 to this model, however, are not based on parameter expansion but are prior estimates for the
 406 remaining unmodeled parameters and are sampling statements where no new data enters the model.
 These prior choices are expressed in Equation 4 and are explained below.

408 For the regression coefficients, such as β^ϕ and γ^ϕ , the chosen priors are considered weakly
 informative as they concentrate most of the probability density between -2 and 2. Similarly, the
 410 scale parameters, such as τ^ϕ and σ^ϕ , are also given weakly informative half-Normal priors which
 concentrate most of the probability density between 0 and -2. The covariance matrices, such as Σ^ϕ ,
 412 are decomposed into a vector of scale terms (e.g. τ^ϕ) and correlation matrices (e.g. Ω^ϕ) which were
 then given weakly informative priors. This approach and choice of LKJ priors for the correlation
 414 matrices follows the Stan User Manual CITATION. For parameter vectors which are presented with

only a single prior (e.g. β^ϕ), that prior statement is for each of the elements of that vector.

$$\begin{aligned}
e &\sim \mathcal{N}(0, \sigma^e) \\
\sigma^e &\sim \mathcal{N}^+(1) \\
\beta^p &\sim \mathcal{N}(0, 1) \\
o^\phi &\sim \mathcal{N}(0, v^\phi) \\
o^\pi &\sim \mathcal{N}(0, v^\pi) \\
v^\phi &\sim \mathcal{N}^+(1) \\
v^\pi &\sim \mathcal{N}^+(1) \\
\beta^\phi &\sim \mathcal{N}(0, 1) \\
\beta^\pi &\sim \mathcal{N}(0, 1) \\
\Sigma^\phi &= \text{diag}(\tau^\phi) \Omega^\phi \text{diag}(\tau^\phi) \\
\Sigma^\pi &= \text{diag}(\tau^\pi) \Omega^\pi \text{diag}(\tau^\pi) \\
\tau^\phi &\sim \mathcal{N}^+(1) \\
\tau^\pi &\sim \mathcal{N}^+(1) \\
\Omega^\phi &\sim \text{LKJ}(2) \\

\sigma^\phi &\sim \mathcal{N}^+(1) \\
\sigma^\pi &\sim \mathcal{N}^+(1) \\
\gamma^\phi &\sim \mathcal{N}(0, 1) \\
\gamma^\pi &\sim \mathcal{N}(0, 1)
\end{aligned} \tag{4}$$

- ⁴¹⁶ The model used in this study is the complete sampling statement expressed through the combination of equations 2, 3, and 4. These statements taken together form a complete generative
⁴¹⁸ model from which posterior inference of parameter values is possible.

Posterior inference and model adequacy

420 A computer program that implements joint posterior inference the model described above (Eqs. 2,
421 3, and 4) was written in the probabilistic programming language Stan (Stan Development Team,
422 2016). All methods for posterior inference implemented in Stan are derivative-based; this causes
complications for actually implementing the above models, because integers do not have derivatives.
424 In order to infer the values of the matrix of latent discrete parameters z (Tables 6) the log posterior
probabilities of all possible states of the unknown values of z were calculated and summed (i.e.
426 marginalized) (Stan Development Team, 2016).

Species durations at minimum range through from a species first appearance to their last
428 appearance in the fossil record, but the incompleteness of all observations means that the actual
times of origination and extinction are unknown. The marginalization approach used here means
430 that the (log) probabilities of all possible histories for a species are calculated, from the end
members of the species having existed for the entire study interval and the species having only
432 existed between the directly observed first and last appearances to all possible intermediaries (Fig
2) (Stan Development Team, 2016). Marginalization is identical, language-wise, to assuming
434 range-through and then estimating the (log) probability of all possible range extension due to
incomplete sampling.

436 The combined size of the dataset and large number of parameters (Eqs. 2, 3, and 4), in specific the
total number of latent parameters that are the matrix z , means that MCMC based posterior
438 inference is computationally slow. Instead, an approximate Bayesian approach was used: variational
inference. A recently developed automatic variational inference algorithm called “automatic
440 differentiation variational inference” (ADVI) is implemented in Stan and is used here (Kucukelbir
et al., 2015; Stan Development Team, 2016). ADVI assumes that the posterior is Gaussian but still
442 yields a true Bayesian posterior; this assumption is similar to quadratic approximation of the
likelihood function commonly used in maximum likelihood based inference (McElreath, 2016). The
444 principal limitation of assuming the joint posterior is Gaussian is that the true topology of the
log-posterior isn’t estimated; this is a particular burden for scale parameters which are bounded to

	Time Bin							
	1	2	3	4	5	6	7	8

Potential	0	0	1	1	1	1	1	0
Potential	0	1	1	1	1	1	1	0
Potential	1	1	1	1	1	1	1	0
Potential	0	0	0	1	1	1	1	1
Potential	0	0	1	1	1	1	1	1
Potential	0	1	1	1	1	1	1	1
Potential	1	1	1	1	1	1	1	1

Figure 2: Conceptual figure of all possible occurrence histories for an observed species. The first row represents the observed presence/absence pattern for a single species at eight time points. The second row corresponds to the known aspects of the “true” occurrence history of that species. The remaining rows correspond to all possible occurrence histories that are consistent with the observed data. By marginalizing over all possible occurrence histories, the probability of each potential history is estimated. The process of parameter marginalization is described in the text.

446 be positive (e.g. standard deviation).

Of additional concern for posterior inference is the partial identifiability of observation parameters
 448 $p_{t=1}$ and $p_{t=T}$ (Royle and Dorazio, 2008). This issue means that the estimates of sampling
 probabilities at the “edges” of the time series cannot fully be estimated because there are no known
 450 “gaps” in species occurrence histories that are guaranteed to be filled. Instead, the values of the first
 and final columns of the “true” presence-absence matrix z for those observations that do not already
 452 have presences in the observed presence-absence matrix y cannot be estimated (Royle and Dorazio,
 2008). The hierarchical modeling approach used here helps mitigate this problem by pulling the
 454 values of $p_{t=1}$ and $p_{t=T}$ towards the overall mean of p (Gelman et al., 2013), and in fact this
 approach might be more analytically sound than the more ad-hoc approaches that are occasionally
 456 used to overcome this hurdle (Royle and Dorazio, 2008). Additionally, because $p_{t=1}$ and $p_{t=T}$ are
 only partially identifiable, estimates of occurrence θ and origination ϕ at $t = 1$ and estimates of θ , ϕ

458 and survival π at $t = T$ may suffer from similar edge effects. Again, the hierarchical modeling
460 approach used here may help correct for this reality by drawing these estimates towards the overall
460 means of those parameters.

462 After obtaining approximate posterior inference using ADVI, model adequacy and quality of fit
464 were assessed using a posterior predictive check (Gelman et al., 2013). By simulating 100 theoretical
466 data sets from the posterior estimates of the model parameters and the observed covariate
468 information the congruence between predictions made by the model and the observed empirical
470 data can be assessed. These datasets are simulated by starting with the observed states of the
472 presence-absence matrix at $t = 1$; from there, the time series roll forward as stochastic processes
with covariate information given from the empirical observations. Importantly, this is fundamentally
different from observing the posterior estimates of the “true” presence-absence matrix z . The
posterior predictive check used in this study is to compare the observed average number of
observations per species to a distribution of simulated averages; if the empirically observed value
sits in the middle of the distribution then the model can be considered adequate in reproducing the
observed number of occurrences per species.

The ADVI assumption of a purely Gaussian posterior limits the utility and accuracy of the
474 posterior predictive checks because parameter estimates do not reflect the true posterior
distribution and are instead just an approximation (Gelman et al., 2013). Because of this, posterior
476 predictive estimates are themselves only approximate checks of model adequacy. The posterior
predictive check that is used in this study focuses on mean occurrence and not to any scale
478 parameters that might be most affected by the ADVI assumptions.

Given parameter estimates, diversity and diversification rates are estimated through posterior
480 predictive simulations. Given the observed presence-absence matrix y , estimates of the true
presence-absence matrix z can be simulated and the distribution of possible occurrence histories
482 can be analyzed. This is conceptually similar to marginalization where the probability of each
possible occurrence history is estimated (Fig. 2), but now these occurrence histories are generated
484 relative to their estimated probabilities.

The posterior distribution of z gives the estimate of standing diversity N_t^{stand} for all time points as

$$N_t^{stand} = \sum_{i=1}^M z_{i,t}. \quad (5)$$

486 Total regional standing diversity can also be partitioned into the standing diversity of each of the
functional groups.

488 **Results**

The results of the analyses described above take one of two forms: direct inspection of posterior
490 parameter estimates, and downstream estimates of diversity and diversification rates based on
posterior predictive simulations.

492 **Posterior parameter estimates**

The model used here in this study appears to have approximately adequate fit to the data based on
494 the results of the posterior predictive check (Fig. 3). Simulated datasets as estimated from the
models' posterior appears similar in terms of average number of occurrences per species to the
496 observed number of occurrences in the empirical mammal dataset.

Log-odds of observing a species given that it is present varies greatly with time (Fig. 4) with lowest
498 log-odds of observation being during the Gerigian and Harrisonian land-mammal ages. It is
important to note, however, that all land-mammal ages with log-odds of observation greater than 2
500 have very high probabilities of observation, which means that while there may be large differences
in log-odds of observation between land-mammal ages this may not translate to substantial
502 difference in the probability of observation.

There is little variance in the effect of functional group on the log-odds of observing a species that
504 is present (Fig. 5). The only functional group with substantially less than expected log-odds of
observation is scansorial insectivores, indicating that the fossil record of this group is the least

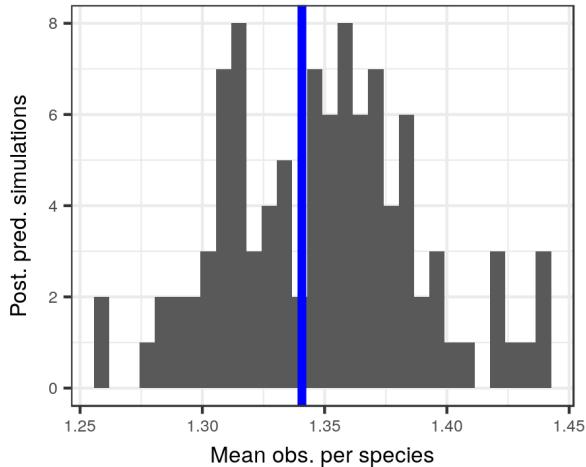

Figure 3: Comparison of the average observed number of occurrences per species (blue line) to the average number of occurrences from 100 posterior predictive datasets using the posterior estimates from the model used in this study. Adequate fit is indicated by the observed value of the test statistic being in the middle of the distribution of those calculated from the simulations.

506 complete of all the functional groups studied. Few functional groups have marginally better than
 expected log-odds of observation, the other insectivorous functional groups have marginally greater
 508 than average log-odds of observation; this is also the case for plantigrade omnivores. These results
 indicate that the observation histories of these functional groups are expected to be complete than
 510 most other functional groups. However, it is important to note that for many functional groups,
 their estimated log-odds of observation are poorly constrained with great uncertainty indicating
 512 little structure in how log-odds of observation varies between functional groups (Fig. 5).

Species mass is found to have a positive effect on probability of observing a species that is present
 514 (Fig. 6). This result indicates that species with greater than average mass are expected to have
 more complete observation histories than species with less than average mass. However, this
 516 estimate does not translate to substantial differences in the estimated probability of observation
 because observation probability is so high for most of the Cenozoic (Fig. 4). In fact, it is only when
 518 land-mammal age observation probability is low that the effect of mass is observable. It is
 important to remember the effect of mass on observation was considered constant over time and
 520 that all differences observation probability between land-mammal ages is driven by variation over
 time. When log-odds of observation is high, differences due to covariate effects translate to very

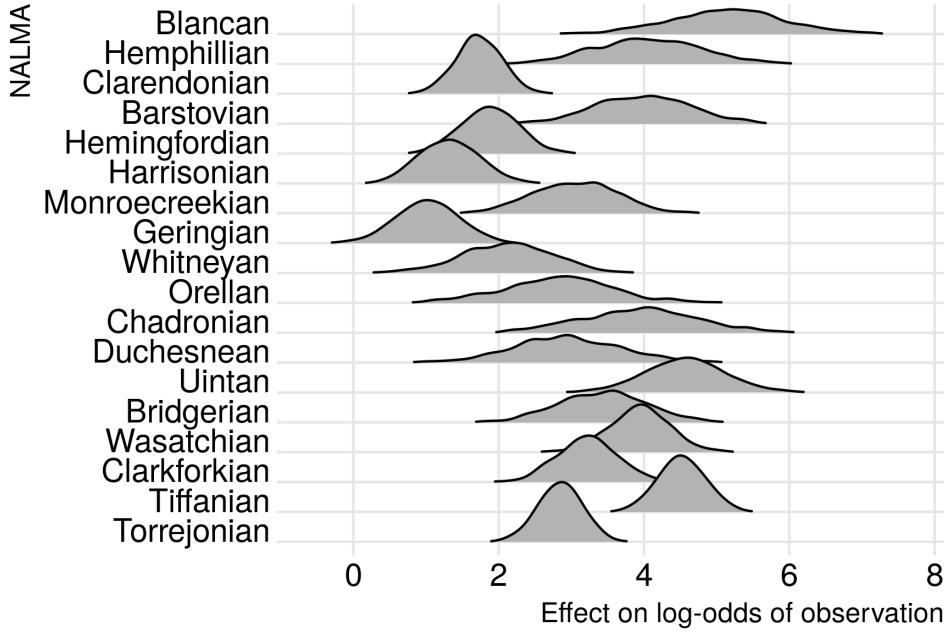

Figure 4: Ridgeline density plots of the estimates for the log-odds of observation from the time-varying intercept term. Each of the named time units are North American land-mammal ages. The oldest land-mammal age is at the bottom of the stack and the youngest is at the top.

522 small differences in actual probability.

Origination probability varies greatly among functional groups with each functional group
 524 exhibiting a unique time series with a few shared features (Fig. 7). When origination probability is
 below 0.50 this means that few if any new species of that functional group are entering the species
 526 pool, and when origination probability is greater than 0.50 new species of that functional group are
 probably entering the species pool. Finally, if origination probability is approximately 0.50, this
 528 indicates that it is equally likely that a new species is entering the species pool as that it is not.
 The slope of origination probability time-series is also very revealing; when the slope of the time
 530 series is positive then new species are being continually being added to the species pool, and when
 the slope is negative then the number of new species entering the pool is decreasing with time.

532 Most of the functional groups have peak origination probability at the present (Fig. 7); new species
 in these functional groups are continually being added to the species pool. In the case of some
 534 functional groups, such as digitigrade carnivores and fossorial herbivores, this is the culmination of

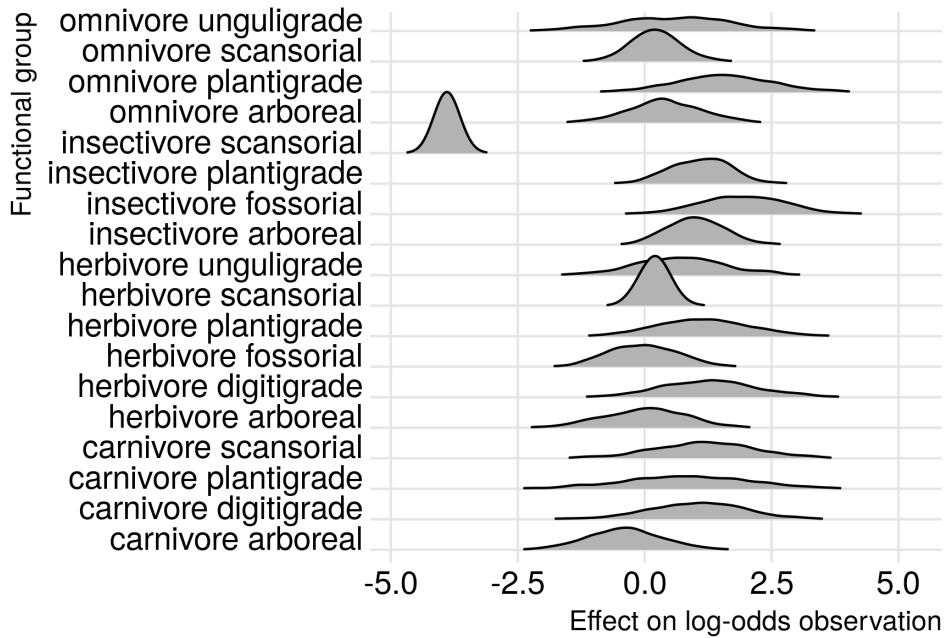

Figure 5: Ridgeline density plots of the estimates of the effect of functional group on log-odds of observation. Each of the rows correspond to a different functional group as indicated by the dietary and locomotor category combination.

those groups continued growth in the species pool. For other functional groups, such as arboreal

536 herbivores, this peak is a reversal from previously relatively low origination probability; this indicates an expansion of these functional groups following a retraction.

538 Five of the functional groups have peak origination probabilities not at the present: arboreal carnivores, arboreal insectivores, plantigrade insectivores, scansorial insectivores, and unguiligrade 540 omnivores. The arboreal functional groups reach peak origination probability in the Paleogene, after which their origination probabilities approach and remain at 0.50, reflecting the loss of these 542 functional groups from the species pool as origination probability never again increases.

Additionally, the uncertainty surrounding in the estimates of origination probability is very large, 544 especially in the Neogene. Large uncertainty in probabilities can reflect complete separation which results from that functional group leaving the species pool and it's (lack of) occurrence is without 546 ambiguity CITATION. The patterns evinced by the other functional groups have similar properties but reach peak origination probability early in the Neogene. Interestingly, origination probability of

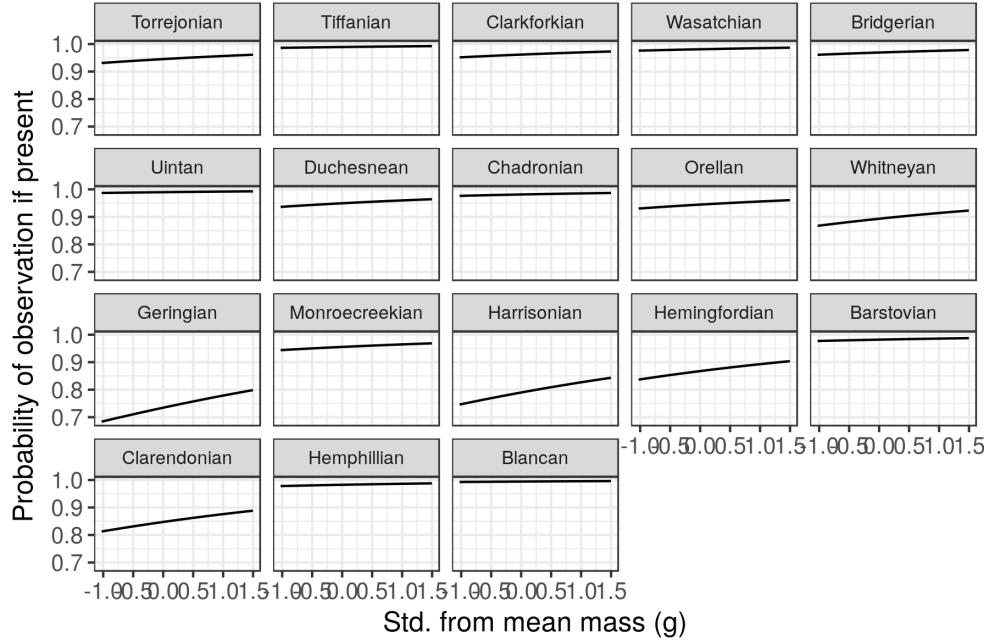

Figure 6: Estimates of the effect of species mass on probability of sampling a present species (p). Mass has been log-transformed, centered, and rescaled; this means that a mass of 0 corresponds to the mean of log-mass of all observed species and that mass is in standard deviation units. Probability of observation is presented for each of the NALMAs where the differences in mean probability of observation are due to variation between the time units (Fig. 4).

548 scansorial insectivores has effectively two peaks, once in the late Paleogene and again in the early
Neogene. Additionally, as will be discussed later in the context of standing diversity, all five of these
550 functional groups decrease in diversity through the Cenozoic.

Origination probability varies greatly amongst mammal orders (Fig. 8). These estimates reflect
552 differences origination probability as well as the relative rarity of that order in the fossil record; if
members of that order appear infrequently, they must have lower probability of origination. Orders
554 with greater than average log-odds of origination include Multituberculata, Dinocerata,
Didelphimorphia, Creodonta, Condylarthra, Cimolesta, and Acroodi. These orders are major
556 components of the Paleogene fossil record. Orders with lower than average log-odds of origination
include Rodentia, Pilosa, Lagomorpha, Eulipotyphyla, Cingulata, Carnivora, and Artiodactyla.
558 These orders are characterized by small body size or primarily Neogene records. Additionally, the
variance between orders is vary large ranging from -3 to 3 log-odds of origination; this large of

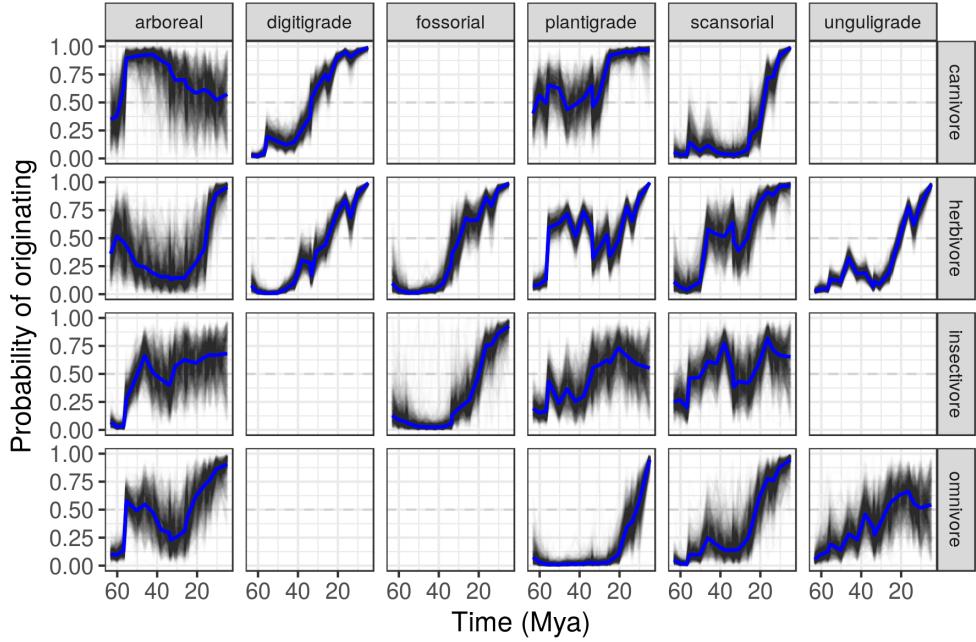

Figure 7: Probability of a mammal functional origination at each time point. Each panel depicts 100 time-series sampled from the model’s posterior. The blue line is the mean origination probability as predicted by the group-level predictors. The columns are by locomotor category and rows by dietary category; their intersections are the observed and analyzed ecotypes.

560 variance reflects how species within these orders have very different patterns of origination independent from their origination based on functional ecology (Fig. 7).

562 Species mass is estimated to have a negative relationship with origination probability (Fig. 9). This result means that species with greater than average mass have a lower probability of originating

564 than species with a below average mass. This result is sensible given the left-skewed distribution of

566 mammal species body sizes where large body sizes form the right-hand tail. There are fewer large

568 body-sized mammals which have originated than small body sized mammals. Interestingly, many of

570 the orders with small body sizes (e.g. Rodentia, Lagomorpha) have below average probabilities of

572 originating (Fig. 8); while not completely kosher, when this result is considered together with the effect of mass on origination these effects could be counteracting each other. These results continue

574 to add to the understanding of the heterogeneity and nuance associated with species origination

576 dynamics.

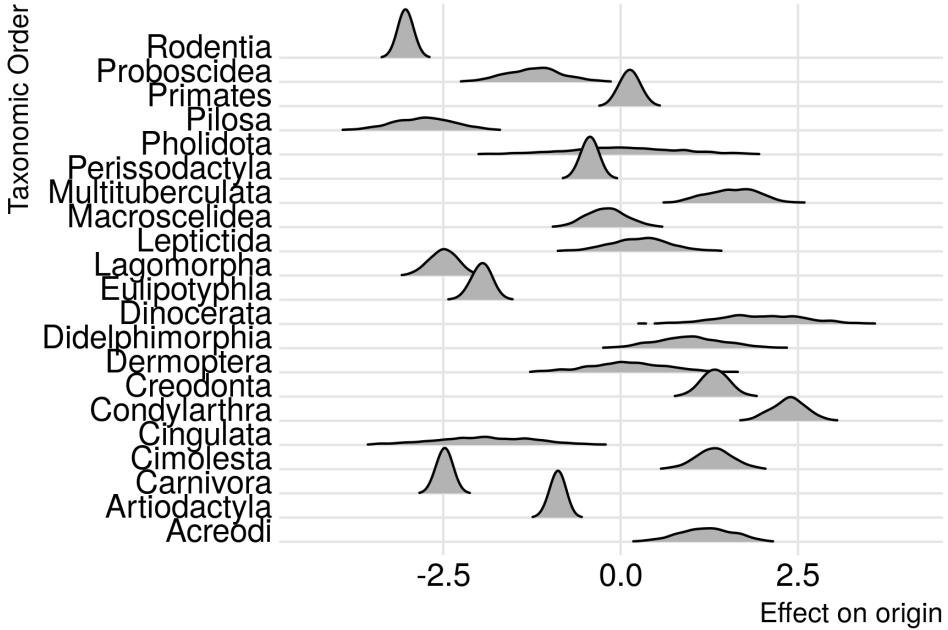

Figure 8: Differences in log-odds of origination based on mammal orders. Positive values correspond to greater log-odds origination than average, while negative values correspond to lower log-odds of origination than average. These estimates reflect the rarity of that order in the fossil record as well as differences in origination.

572 The survival probability time-series vary greatly between each of the functional groups with each
 573 exhibiting unique patterns (Fig. 12). Interestingly, unlike origination probability (Fig. 7), survival
 574 probability is frequently estimated with considerable uncertainty. When survival
 575 probability is below 0.50 then a species that is present is unlikely to survive from one time unit to
 576 the next, while when survival probability is greater than 0.50 species can be expected to survive to
 577 the next time unit. Finally, when survival probability is approximately 0.50 then survival and
 578 extinction are equally likely. Overall, survival probability is rarely estimated to be greater than 0.50
 579 with any certainty. This result is consistent with the average occurrence being <1.35 time unit per
 580 species which means that a plurality of species have only a single temporal occurrence (Fig. 3).

The survival probability of many functional groups is frequently approximately 0.50, indicating
 581 extinction is frequently random with respect to functional group (Fig. 12). For example, the
 582 survival probability scansorial canivores is approximately 0.50 for the entire time series which
 583 indicates that there is no best or worst time for this functional groups survival. Similar patterns can

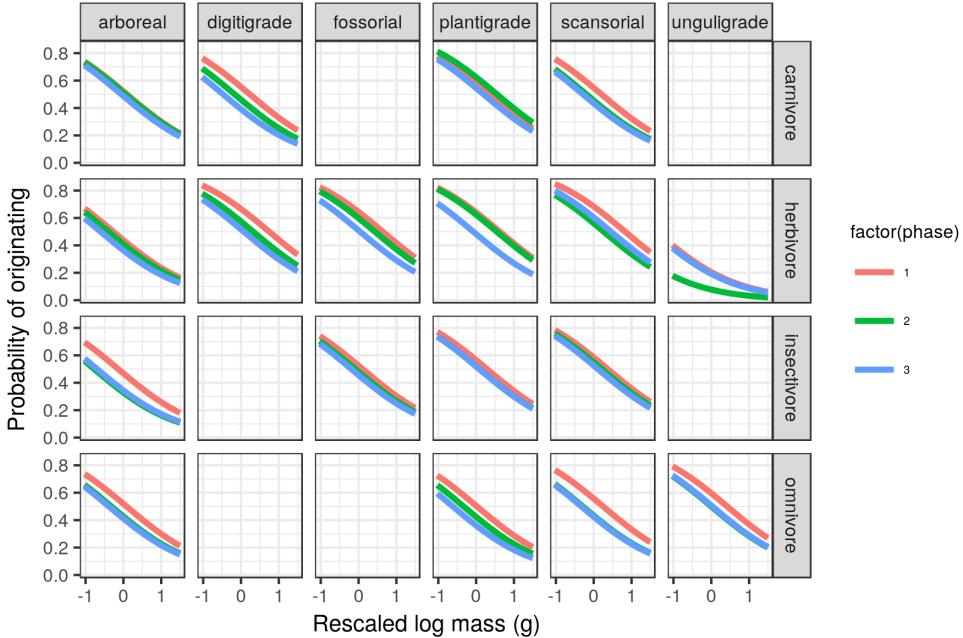

Figure 9: Mean estimate of the effect of species mass on the probability of a species originating for each of the three plant phases. The effect of mass is considered constant over time and that the only aspect of the model that changes with plant phase is the intercept of the relationship between mass and origination. The three plant phases are indicated by the color of the line. Mass has been log-transformed, centered, and rescaled; this means that a mass of 0 corresponds to the mean of log-mass of all observed species and that mass is in standard deviation units. For clarity, only the mean estimates of the effects of mass and plant phase are plotted.

be observed for mean survival probability of arboreal omnivores, fossorial insectivores, and

586 plantigrade omnivores though all three of these groups have sudden drops in survival probability in
approximately the last 10Mya.

588 Arboreal herbivores are the only functional group for which survival probability is approximately
above 0.50 for the entire Cenozoic (Fig. 12). This result indicates that when an arboreal herbivore
590 species is present it is expected to survive from one time unit to the next. However, it is important
to note that arboreal herbivores are estimated to have an origination probability below 0.50 for
592 most of the Cenozoic. Together, these results mean that arboreal herbivore species are rare but are
expected to survive from one time point to the next.

594 A common feature of multiple functional group's survival probability time-series is a peak in
survival during the Neogene (Fig. 12). In most cases, these peaks are estimated with little

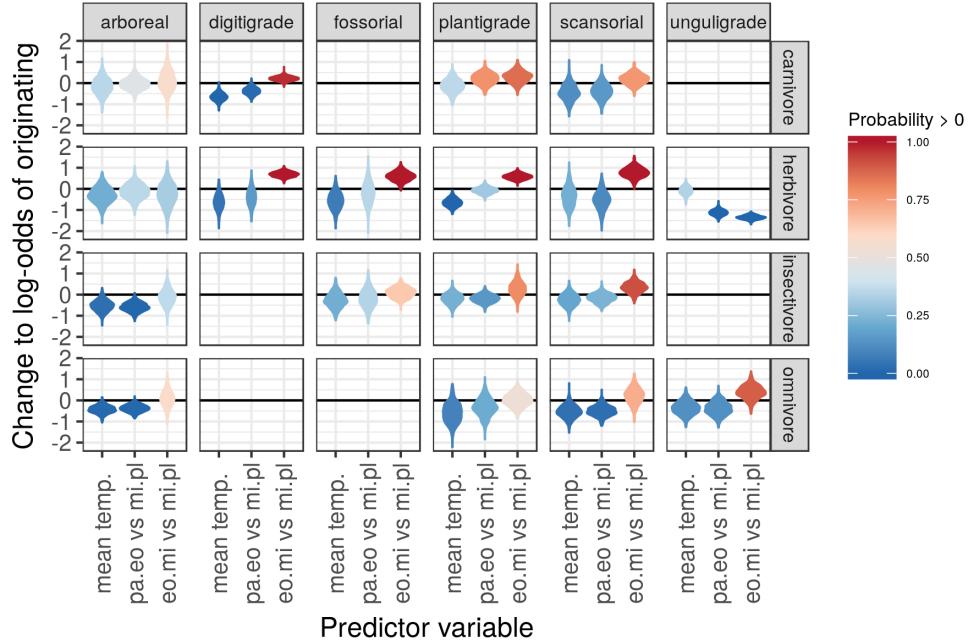

Figure 10: Estimated effects of the group-level covariates describing environmental context on log-odds of species origination. These estimates are from the birth-death model. What is plotted is a violin of the distribution of 1000 samples from the approximate posterior. The effect of plant phase graphed here is calculated as Phase 1= $\gamma_{phase\ 1}$, Phase 2= $\gamma_{phase\ 1} + \gamma_{phase\ 2}$, and so on.

596 uncertainty which indicates how apparent this event is. Digitigrade carnivores, digitigrade
 597 herbivores, plantigrade herbivores, scansorial insectivores, unculigrade herbivores, and unculigrade
 598 omnivores all peak in survival probability at approximately 25Mya. This peak in survival means
 599 that species of these functional groups which are unlikely to go extinct at this point, potentially
 600 indicating favorable environmental conditions for these groups at the Paleogene-Neogene transition.
 Additionally, this peak does not coincide with the movement from one plant phase to another
 602 (Table 4).

Species mass is estimated to have no relationship or at best a weakly positive relationship with
 604 survival probability (Fig. 14). This result means that differences in mass do not lead to differences
 605 in species survival. This result is consistent with previous studies of North American species and
 606 genus survival dynamics CITATION SMITS TOMIYA, and implies that other ecological factors
 have greater importance on survival than mass alone. GET PROBABILITY ESTIMATE

unguligrade omnivore	0.888	0.127	0.960

- 608 Functional group survival probability is rarely associated with differences between the three plant
phases (Table 11) with only five pair-wise comparisons having greater than 89% probability of
610 differences in survival between phases. Unuligrade herbivores have an approximately 89%
probability of having lower survival probability during the Paleocene-Eocene than the
612 Miocene-Pleistocene. For digitgrade herbivores, and unuligrade omnivores, the Eocene-Miocene
phase have an approximately 90% probability of having greater survival probability than during the
614 Miocene-Pleistocene phase. In contrast, unuligrade herbivores are estimated to have lower
survival probability in the Eocene-Miocene phase than the Miocene-Pleistocene phase. Finally,
616 unuligrade herbivores have an approximately 99% probability of having a lower survival
probability during the Paleocene-Eocene than the Eocene-Miocene.
- 618 Temperature is estimated to have no effect on functional group survival probability (Table 12).

Table 10: Posterior probability that the effects of the two temperature covariates on the log-odds of an ecotype origination are greater than 0. What is estimated is the probability that these estimates are greater than 0; high or low probabilities indicate the “strength” of the covariate in that direction (positive and negative, respectively). These estimates are from the birth-death model.

Analysis of diversity

- 620 All of the analyses of diversification and macroevolutionary rates has been done using only the
 birth-death model because of the model’s better posterior predictive check performance (Fig. 3).
- 622 The general pattern of the estimated North American total mammal diversity for the Cenozoic is
 “stable” in that diversity fluctuates around a constant mean standing diversity, does not fluctuate
 624 wildly and rapidly over the Cenozoic, and demonstrates no sustained directional trends (Fig. 17a).
 In broad strokes, the first 15 or so million years of the Cenozoic are characterized by first an
 626 increase and then a decline in standing diversity at approximately 45-50 Mya (early-middle Eocene).
 Following this decline, standing diversity is broadly constant from 45 to 18 Mya (early Miocene).
 628 After this, there is a rapid spike in diversity followed by a slight decline in diversity up to the
 Recent.

630 The pattern exhibited by the diversity history estimated in this study (Fig. 17a) has some major
similarities with previous mammal diversity curves (Alroy, 2009): both curves begin with an
632 increase in diversity most of the major increases in diversity are retained including the large
diversity spike during the Miocene. Unlike subsampling based approaches to estimating diversity
634 (Alroy, 2010), I'm able to interpolate over unsampled/poorly sampled time periods because of how
the hierarchical model can share information across the different units Gelman et al. (2013); for
636 cases like unsampled temporal bins, this may lead to estimates with high uncertainty, but that is
preferable to no estimate at all. Finally, the Bayesian framework here gives a distribution of
638 possible estimates of diversity allowing for direct inspection of the uncertainty of our inferences,
something that is preferable to both traditional and resampling based confidence interval estimates
640 (Gelman et al., 2013). Note that my time series of estimated diversity begins at a slightly different
point than that of Alroy (2009) and that the time intervals used by Alroy (2009) are slightly shorter
642 than those used here, so this may cause some of the minor differences between the curves. Also,
please note that the diversity values are plotted at the “ceiling” of each temporal interval and not

Table 12: Posterior probability that the effects of the two temperature covariates on the log-odds of an ecotype survival are greater than 0. What is estimated is the probability that these estimates are greater than 0; high or low probabilities indicate the “strength” of the covariate in that direction (positive and negative, respectively). These estimates are from the birth-death model.

644 at the midpoint (Fig. 17a).

When viewed through the lens of diversification rate, some of the structure behind the estimated
646 diversity history begins to take shape (Fig. 17b). For most of the Cenozoic, the diversification rate
hovers around zero, punctuated by both positive and negative spikes. The largest spike in
648 diversification rate is at 16 Mya, which is early Oligocene (Fig. 17b). Other notable increases in
diversification rate occur 56, 46, 22, 18, and 6 Mya (Table 13), though the last of these may be due
650 to edge effects surrounding the partial-identifiability of $p_{t=T}$. Notable decreases in diversification
rate occur at 54, 50, 48, 44, 40, 34, 30, 24, 20, 16, 12, and 8 Mya (Table 13), meaning that
652 diversification rate has more major decreases than increases. While diversification rates significantly
lower than average are more common than diversification rates greater than average, when
654 diversification rate does increase it is with a greater magnitude than most decreases (Fig. 17b).
Given that diversification rate more closely resembles origination rate than extinction rate (Fig.

656 17b, ??, ??), these decreases in diversification rate may be indicative of “depletions” (failure to
replace extinct taxa) rather than pulses of extinction.

658 The estimates from this study of per capita origination and extinction rates for the entire species
pool (Fig. ??, ??) are very different from the origination and extinction rates estimated by Alroy
660 (2009). The two most striking difference are the very different estimates of extinction rate between
the two studies and the very different scales of the origination rate estimates. This may be due to
662 the fundamentally different way these rates are calculated, and how the diversification process was
modeled. The per capita rates estimated in this study follow straight from the definition of a per
664 capita rate (e.g. number of originations between time t and $t + 1$ divided by the diversity at time t)
while the rates calculated in Alroy (2009) are based on log ratios of standing diversity.

666 The comparison between per capita origination and extinction rate estimates reveals how
diversification rate is formed (Fig. ??, ??). As expected given previous inspection of the ecotype
668 specific estimates of origination and survival probabilities from the birth-death model,
diversification rate seems most driven by changes in origination rate as opposed to extinction rate.
670 Extinction rate, on the other hand, demonstrates an almost saw-toothed pattern around a constant
mean (Fig. ??). These results are broadly consistent with those from previous analyses of North
672 American mammals diversity and diversification (Alroy, 1996, 2009; Alroy et al., 2000).

Diversity partitioned by ecotype reveals a lot of the complexity behind the pattern of mammal
674 diversity for the Cenozoic (Fig. 18).

Arboreal ecotypes obtain peak diversity early in the Cenozoic and then decline for the rest of the
676 time series, becoming increasingly rare or absent as diversity approaches the Recent (Fig. 18).

Arboreal herbivores and omnivores obtain peak diversity at the beginning of the Cenozoic then go
678 into decline while remaining a small part of the species pool, while arboreal carnivores and
insectivores obtain peak diversity 52-50 Mya and then quickly decline and become extremely rare or
680 entirely absent from the species pool. This is consistent with increasing extinction risk in the
Neogene compared to the Paleogene as proposed by Smits (2015).

682 The diversity of digitigrade and unguligrade herbivores increases over the Cenozoic (Fig. 18). In

Table 13: Posterior probabilities of diversity N_t^{stand} or diversification rate D_t^{rate} being greater than average standing diversity \bar{N}^{stand} or average diversification rate \bar{D}^{rate} for the whole Cenozoic. The “Time” column corresponds to the top of each of the temporal bins. Diversification rate can not be estimated for the last time point because it is unknown how many more species originated or went extinct following this temporal bin. The estimates are from the birth-death model.

contrast, plantigrade herbivore diversity does not have a single, broad-strokes pattern; instead,

684 diversity increases, decreases, and may have then increased till the Recent. In contrast, fossorial and
 685 scansorial herbivores demonstrate a much flatter history of diversity, with a slight increase in
 686 diversity that over time is more pronounced among fossorial taxa than scansorial taxa. The
 687 expansion of digitigrade and unguligrade herbivores over the Cenozoic is consistent with the
 688 gradual expansion of grasslands which these ecotypes are better adapted to than closed
 environments (Blois and Hadly, 2009; Strömberg, 2005).

690 Digitigrade carnivores have a multi-modal diversity history, with peaks at 54-52 and 12-10 Mya
 (Fig.18). Between these two peaks digitigrade carnivore diversity dips below average diversity
 692 following the first peak and then grows slowly until the second peak. Plantigrade carnivores obtain
 693 peak diversity in the early Cenozoic and then maintain a relatively stable diversity until another
 694 peak at the end of the Cenozoic. The generally flat diversity history digitigrade carnivores lacks any

sustained temporal trends and seems to reflect previous findings of limited diversity in spite of
696 constant turnover and morphological evolution (Silvestro et al., 2015; Slater, 2015; Van
Valkenburgh, 1999)

698 There are some broad similarities in diversity histories of insectivorous and omnivorous taxa. The
diversity histories of arboreal, plantigrade, and scansorial insectivorous taxa all demonstrate a
700 decreasing pattern with time, while fossorial insectivores have a flat diversity history with a peak
approximately 10 Mya (Fig. 18). Arboreal and scansorial omnivores decrease in diversity from their
702 initial peaks early in the Cenozoic, and plantigrade omnivores have a generally flat diversity history
with a sudden peak in diversity late in the Cenozoic (Fig. 18). Unguligrade omnivores also
704 demonstrate a possible decrease in diversity over the Cenozoic, but not as clearly as arboreal and
scansorial omnivores.

706 The waxing and waning of the mammal ecotypes is obvious when comparing changes to estimated
relative log-mean of diversity (Fig. 19). While ecotype diversity does appear to change gradually,
708 there are definite changes to the relative contributions of the ecotypes to the regional species pool.
All arboreal ecotypes clearly decrease in relative diversity over the Cenozoic. In contrast the the
710 digitigrade herbivore, fossorial herbivore, scansorial herbivore, and unguligrade herbivore ecotypes
which increase in relative diversity over the Cenozoic. The digitigrade carnivore ecotype increases in
712 relative diversity until approximately the start of the Neogene, after which it maintains a generally
constant relative diversity; this is consistent with previous observations of constant or
714 density-dependent diversity of the canid guild for the Neogene (Silvestro et al., 2015; Slater, 2015;
Van Valkenburgh, 1999), a guild that overlaps with the digitigrade carnivore ecotype. Plantigrade
716 herbivores remain a constant relative contribution to ecotypic diversity. These results support the
hypothesis of a gradual transition from the early Paleogene with a region with more available
718 habitat for arboreal taxa and less available habitat for many digitigrade and unguligrade taxa, to an
environment where arboreal taxa are absent from the species pool and digitigrade and unguligrade
720 taxa are much more dominant (Fig. 19). It is the relative contributions of digitigrade carnivores,
digitigrade herbivores, and unguligrade herbivores which really shape the regional species pool of
722 the Neogene.

Many of the estimated ecotype-specific diversity histories share a similar increase in diversity in the
724 late Cenozoic, 16-14 Mya (Fig. 18). These increases are either sustained or temporary and are seen
in digitigrade carnivores, plantigrade carnivores, scansorial carnivores, unguligrade herbivores,
726 fossorial insectivores, and plantigrade omnivores.

Discussion

728 Both the composition of a species pool and its environmental context change over time, though not
necessarily at the same rate or concurrently. Local communities, whose species are drawn from the
730 regional species pool, have “roles” in their communities defined by their interactions with a host of
biotic and abiotic interactors (i.e. a species’ niche). For higher level ecological characterizations like
732 ecotypes and guilds, these roles are broad and not defined by specific interactions but by the genre
of interactions species within that grouping participate in. The diversity of species within an
734 ecotype or guild can be stable over millions of years despite constant species turnover (Jernvall and
Fortelius, 2004; Slater, 2015; Van Valkenburgh, 1999). This implies that the size and scope of the
736 role of an ecotype or guild in local communities, and the regional species pool as a whole, is
preserved even as the individual interactors change. This also implies that the structure of regional
738 species pools can be constant over time despite a constantly changing set of “players.” There is
even evidence that functional groups are at least partially self-organizing and truly emergent
740 (Scheffer and van Nes, 2006).

Comparison of the results from the posterior predictive checks for the pure-presence and birth-death
742 models supports the conclusion that regional species pool dynamics cannot simply be described by
a single occurrence probability and are instead the result of the interplay between the origination
744 and extinction processes. Additionally, changes to the ecotypic composition and diversification rate
of the North American regional species pool are driven primarily by variation in origination and not
746 extinction (Fig. 17). These aspects of how regional species pool diversity is shaped are not directly
observable in studies of the Recent where time scales are short and macroevolutionary dynamics are
748 inferable solely from phylogeny (Fritz et al., 2013; Price and Schmitz, 2016).

Extinction rate for the entire regional species pool through time is highly variable and demonstrates
750 a saw-toothed pattern with no obvious temporal trends. While a constant mean extinction rate is
consistent with previous observation (Alroy, 1996; Alroy et al., 2000), the degree to which mammal
752 extinction rate is actually variable may not have been equally appreciated as it has been for the
marine invertebrate record (Foote, 2000a,b, 2006, 2010). What is most consistent with previous
754 observations, however, is that diversity seems to be most structured by changes to origination
rather than changes to extinction (Alroy, 1996; Alroy et al., 2000).

756 Comparison of the ecotype specific diversity histories adds a considerable degree of nuance to broad
narrative of shifts in functional composition of the North American mammal species pool as being
758 gradual (Fig. 18). While most ecotypes do not experience sudden shifts in origination or extinction
rate (Fig. ??, ??). As with the diversification rate of the entire species pool, the diversification of
760 individual ecotypes seem principally driven by origination and not extinction. Instead, while species
seem to originate in waves (Fig. ??), they appear to leave the regional species pool in an
762 uncoordinated and individual manner (Fig. ??) which could be considered consistent with the
maxim that all species respond differently to environmental change (Blois and Hadly, 2009). Note,
764 however, this result characterizes the entire North American mammal regional species pool and
thus may not reflect the dynamics of individual local communities.

766 The few large-magnitude, but temporary, increases in ecotype-specific origination rate occur in
digitigrade carnivores, digitigrade herbivores, plantigrade herbivores, and unguligrade herbivores.
768 Importantly, the large peak in diversification and origination rates 16 Mya (Fig. 17) appears driven
almost entirely by a massive increase in the origination rate of unguligrade herbivores (Fig. ??).
770 Additionally, there is some evidence that the origination probabilities of these ecotypes are
correlated (Fig. 11, ??). While this result does not mean that there are large and sudden
772 cross-ecotype changes to the regional species pool, it does suggest that additions to the species pool
do not occur in individual ecotypes idiosyncratically.

774 Arboreal taxa disappear from the regional species pool over the Cenozoic, with long term decline
over the Paleogene leading to the disappearance by start of Neogene ~22 Mya. This is partially

776 consistent with one of the two possible patterns presented here and in Smits (2015) that would
777 result in arboreal taxa having a greater extinction risk than other ecotypes: the Paleogene and
778 Neogene were different selective regimes and, while the earliest Cenozoic may have been neutral
779 with respect to arboreal taxa, they disappeared quickly over the Cenozoic which may account for
780 their higher extinction risk. However, these result add some nuance to this scenario as arboreal taxa
781 were declining throughout the Paleogene instead of maintaining a flat diversity as hypothesized
782 (Smits, 2015). I interpret the decline of arboreal taxa through out the Paleogene to mean that the
783 shift from closed to open environments began in the Paleogene and led to increasingly hostile
784 environments for arboreal taxa as opposed to being a sudden change in selective regime between
785 the Paleogene and Neogene. In addition to all arboreal taxa, the diversity of plantigrade and
786 scansorial insectivores decreases with time (Fig. 18).

Digitigrade carnivores have a relatively stable diversity history through the Cenozoic and can be
788 characterized as varying around a constant mean diversity. This ecotype has a large amount of
overlap with the carnivore guild which has been the focus of much research (Janis and Wilhelm,
790 1993; Pires et al., 2015; Slater, 2015; Van Valkenburgh, 1999). This result is consistent with some
form of “control” on the diversity of this ecotype, such as diversity-dependent diversification
792 (Silvestro et al., 2015; Slater, 2015; Van Valkenburgh, 1999).

Both digitigrade and unguligrade herbivores increase in diversity over the Cenozoic. The increase of
794 these cursorial forms is consistent with the gradual opening up of the North American landscape
(Blois and Hadly, 2009; Graham, 2011; Strömberg, 2005) and may indicate a long-term shift in the
796 interactors associated with those ecotypes leading to increased contribution to the regional species
pool. This result may be comparable to the increasing percentage of hypsodont (high-crowned
798 teeth) mammals in the Neogene of Europe being due to an enrichment of hypsodont taxa and not
a depletion of non-hypsodont taxa. Smaller scale increases in fossorial herbivore species, and a lesser
800 extent plantigrade herbivores, suggests that the increase of interactors may be associated mostly
with the herbivore dietary category with locomotor category tempering that relationship. These
802 results support the conclusion that the increase in digitigrade and unguligrade herbivores is the
result of an enrichment of these ecotypes as opposed to being caused by the depletion of other

804 herbivorous ecotypes; this is further supported by the lack of major changes to the number of
extinctions of all herbivore ecotypes (Fig. ??).

806 An association between plant phase and differences in ecotype occurrence or origination-extinction
probabilities is interpreted to mean that an ecotype enrichment or depletion is due to associations
808 between that ecotype and whatever plants are dominant at that time. Plant phase clearly
structures the occurrence and origination probability time series (Fig. ??, 7). These differences in
810 occurrence or origination translate to the estimates of diversity and diversification rate; the largest
spike in diversity, diversification rate, and origination rate all correspond to the onset of the last
812 plant phase (Fig. 17). The clearest example of the diversity of an ecotype increasing at this
particular transition is in scansorial carnivores (Fig. 18); similar shifts in other ecotypes are much
814 more subtle, as was previously noted for fossorial insectivores.

Interestingly, for all of the ecotypes with sudden changes in diversity at this transition the change is
816 an increase, even if only temporarily. There are two interpretations of these results. A biological
interpretation of this result is that, because plant phase associations are only with occurrence or
818 origination probabilities and not survival, these ecotypes were well suited for the newly available
mammal-plant interactions due to the increased modernization of their floral context (Graham,
820 2011). Alternatively, the increase in diversity associated with the third plant phase may be caused
by the edge effect in origination probability that is artificially inflating the number of origination
822 events (Fig. 7). However, the estimated number of origination events does not have a tremendous
spike at this transition, nor is a major increase in the number of origination events sustained (Fig.
824 ??).

There are fewer, less obvious shifts in diversity surrounding the transition from the first to second
826 plant phase, with the following ecotypes having apparent shifts in diversity at 50 My: plantigrade
carnivores (down), arboreal omnivores (down), and scansorial omnivores (down). Arboreal
828 insectivore peak diversity also occurs 50 Mya, and is then followed by a steep decline in diversity
till 30 Mya when this ecotype is lost from the species pool. Because plant phase has been found to
830 structure occurrence/origination (Fig. ??, 7), but not survival (Fig. 12), my interpretation of these

results is that new species were not entering the system because there were fewer available
832 mammal-plant interactions available for those ecotypes. Instead, these ecotypes were poorly suited
for the newly available mammal-plant interactions brought upon by the changing environmental
834 context (Graham, 2011).

The temperature covariates are found to have similar effects on occurrence and origination
836 probabilities (Tables ??, 10). Temperature is found to more often affect ecotype occurrence
probabilities than origination probabilities. In most cases, there is a negative association between
838 temperature and probability of occurring or first originating; this means that if temperature
decreases, we would then expect an increase in the probability of occurring or first originating. In
840 contrast, temperature range is estimated to be a good predictor of survival in only to mammal
ecotypes and only marginally for one of those (Table 12). Additionally, both of these cases have
842 positive relationships, meaning that if temperature decreases it is expected that species survival will
also decrease.

844 The result that temperature does not affect the survival probability of most ecotypes is consistent
with previous analysis of mammal diversity (Alroy et al., 2000). The result that temperature affects
846 origination probability, on the other hand, is in strong contrast to the results Alroy et al. (2000).
An important difference between the analyses presented here and that of Alroy et al. (2000) is I am
848 considering the effect of temperature on the probability of a species originating, assuming it hasn't
originated yet while Alroy et al. (2000) analyzes the correlation between the first differences of the
850 origination and extinction rates with an oxygen isotope curve (Zachos et al., 2001). Origination or
extinction rates have very different properties than the origination probabilities estimated here
852 brought upon by the difference both in definition and units. Origination probability is the expected
probability that a species that has never been present and is not present at time t will be present at
854 time $t + 1$; origination probability is defined for a single species. In contrast, per capita rates are
defined (for origination) as the expected number of new species to have originated between time t
856 and $t + 1$ given the total number of species present at time t ; per capita rates are defined for the
standing diversity. It is also important to note that even though there is an edge effect at the last
858 time interval that causes an increase in the occurrence and origination probabilities of some

ecotypes (Fig. ??, 7, the corresponding rates and population level birth/death dynamics do not
860 share that pattern (Fig. 17, ??, ??). However, it is still possible that the finding that temperature
has an effect on origination may simply be because as time approaches the present the number of
862 species which have originated increases and not because of climatic forcing of origination.

All environmental factors are found to affect the occurrence and origination probabilities for most,
864 but not all, mammal ecotypes (Fig. ??, 10). In contrast, the environmental factors probably do not
affect differences in ecotype survival probability (Fig. 15). The focus in previous research on
866 temperature and major climatic or geological events without other measures of environmental
context may have led to confusion in discussions of how the “environment” affects mammal
868 diversity and diversification (Alroy et al., 2000; Figueirido et al., 2012). The environment or climate
are more than just global or regional temperature, it is also the set of all possible biotic and abiotic
870 interactions that can be experienced by a member of the species pool. By including more
descriptors of species’ environmental context than simple an estimate of global temperature a more
872 complete “picture” of the diversification process is inferred.

Analysis of relationship between temperature and origination rate is probably better suited for a
874 continuous-time birth-death or multilevel stochastic differential equation model instead of a
discrete-time model because the both continuous models estimate rates while discrete time models
876 estimate probabilities (Allen, 2011). The PyRate model(s) are based on a continuous-time
birth-death process (Silvestro et al., 2015, 2014). Unfortunately, a continuous-time model may be
878 unsuited for most paleontological data as the fossil record is naturally discrete; fossils are assigned
to temporal units, such as stages, which have age ranges. Individual fossils are not assigned
880 individual numeric ages. This reality was in fact my one of motivations for using discrete-time
birth-death model instead of one in continuous-time. There are of course exceptions to this
882 characterization; the fossil record of graptolites from the Ordovician and Silurian (Crampton et al.,
2016) and the fossil record of some mammal orders from Neogene are of high enough resolution that
884 the application of continuous-time models is appropriate and less fraught.

The effect of species mass on either occurrence or origination and extinction was not allowed to

886 vary by ecotype or environmental context. The primary reason for this modeling choice was that
this study focuses on ecotypic based differences in either occurrence, or origination and extinction.
888 Allowing the effect of body size to vary by ecotype, time, and environmental factors would increase
the overall complexity of the model beyond the scope of the study. Instead, body size was included
890 in order to control for its possible underlying effects (McElreath, 2016). A control means that if
there is variation due to body mass, having a term to “absorb” that effect is better than ignoring it.
892 The only covariate allowed to affect sampling probability was mass and only as a linear predictor.
Other covariates, such as the environmental factors considered here, could have affected the
894 underlying preservation process that limits sampling probability; their exclusion as covariates of
sampling/observation was the product of a few key decisions: model complexity, model
896 interpretability, the scope of this study, and a lack of good hypotheses related to these covariates to
warrant their inclusion.

898 Conclusions

These results add a considerable degree of nuance to the narrative of changes to North American
900 diversity being gradual. My results support the conclusions that ecotypic diversity is shaped more
by changes to origination than extinction and that major changes to total diversification rate can
902 be attributed to increases in origination of only some ecotypes. There are a number of interesting
estimated ecotype diversity patterns. While arboreal ecotypes are diverse in the Paleogene, by the
904 Neogene all arboreal ecotypes dramatically decreased in diversity and became either rare or absent
from the regional species pool. The other ecotypes that decrease in diversity over the Cenozoic are
906 plantigrade and scansorial insectivores and scansorial omnivores. The only ecotypes that
demonstrate a sustained pattern of increasing diversity are digitigrade and unguligrade herbivores.
908 When the environmental covariates analyzed here are inferred to affect the diversification of an
ecotype, this effect is virtually always on origination and not survival. This analysis provides a
910 much more complete picture of North American mammal diversity and diversification, specifically
the dynamics of the ecotypic composition of that diversity. By increasing the complexity of analysis

912 while precisely translating research questions into a statistical model, the context of the results is
913 much better understood. Future studies of diversity and diversification should incorporate as much
914 information as possible into their analyses in order to better understand or at least contextualize
the complex processes underlying that diversity.

916 Acknowledgements

I would like to thank K. Angielczyk, M. Foote, P. D. Polly, R. Ree, and G. Slater for helpful
918 discussion and advice. This entire study would not have been possible without the Herculean
effort of the many contributors to the Paleobiology Database. In particular, I would like to thank J.
920 Alroy and M. Uhen for curating most of the mammal occurrences recorded in the PBDB. This is
Paleobiology Database publication XXX.

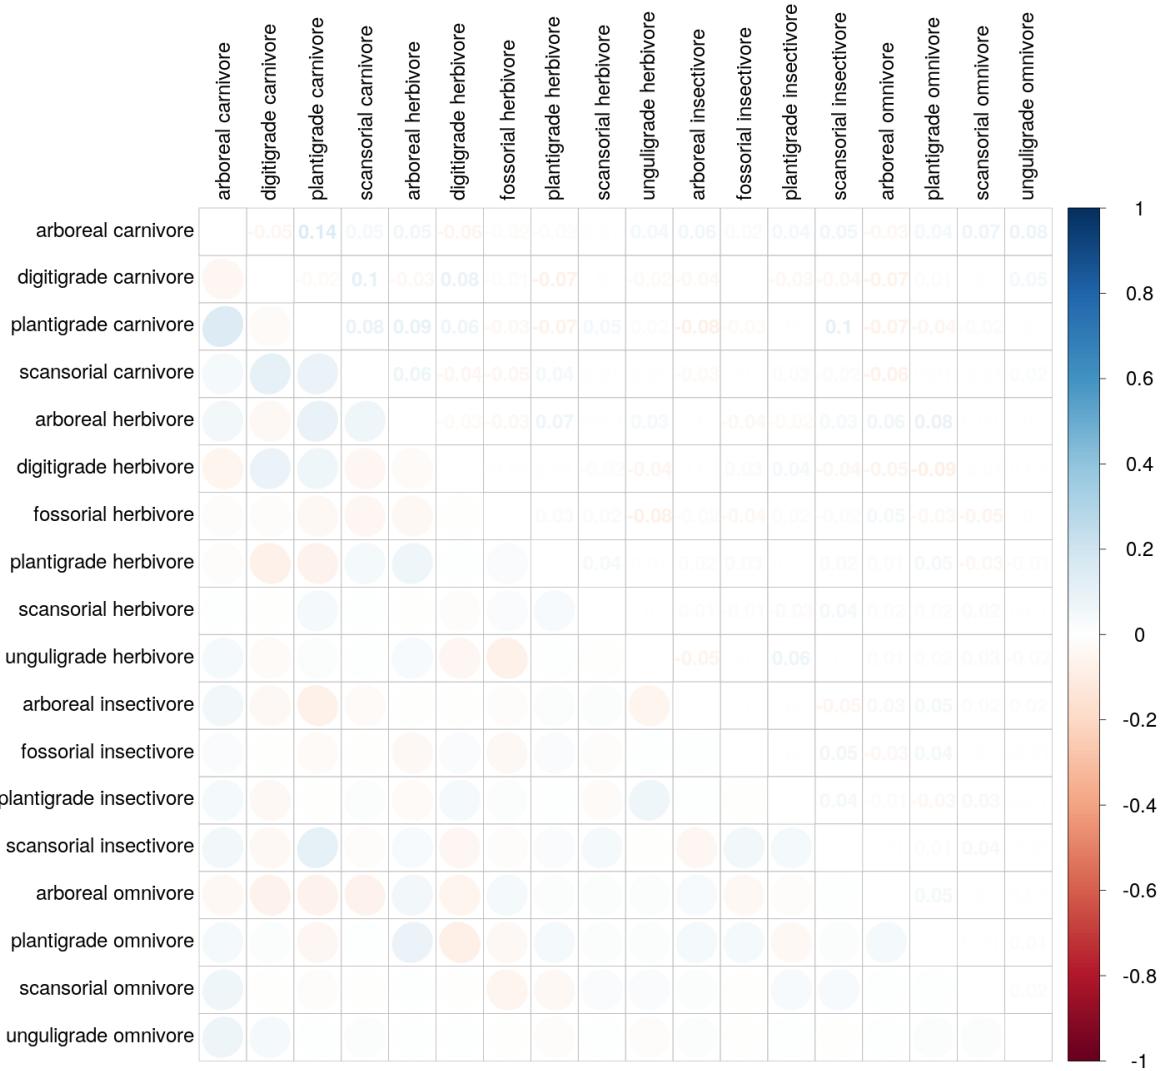

Figure 11: Posterior mean estimates of the correlations in origination probability between the mammal ecotypes. The lower triangle of the matrix is populated with ellipses corresponding to the level of correlation between the two ecotypes, while the upper triangle of the matrix corresponds to the mean estimated correlation between ecotypes. Darker values correspond to a greater magnitude of correlation with blue values corresponding to a positive correlation and red values a negative correlation.

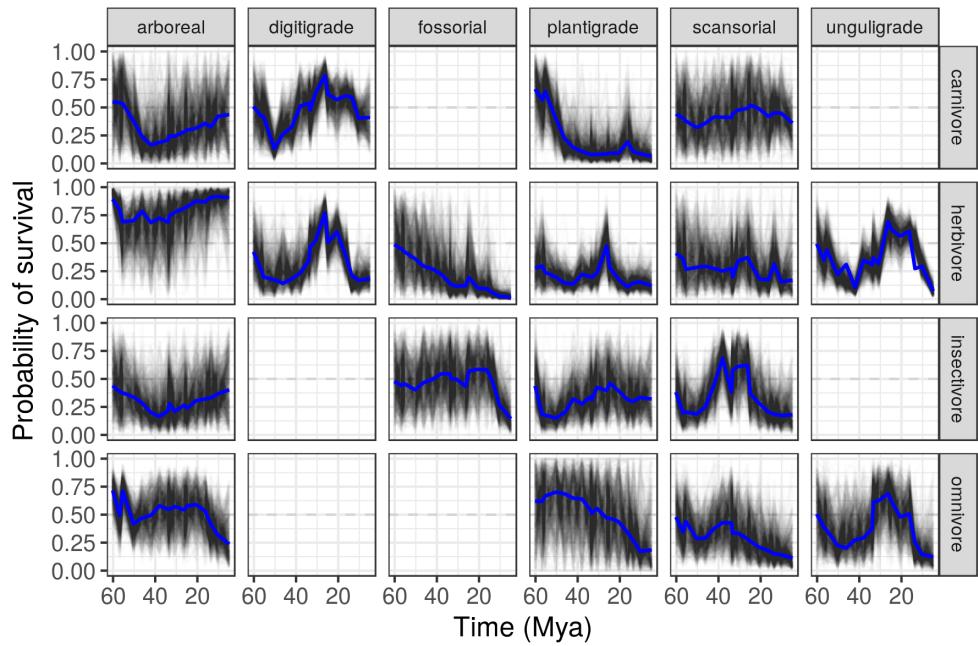

Figure 12: Probability of a mammal ecotype survival probabilities at each time point as estimated from the birth-death model. Each panel depicts 100 random samples from the model's posterior. The columns are by locomotor category and rows by dietary category; their intersections are the observed and analyzed ecotypes. Panels with no lines are ecotypes not observed in the dataset.

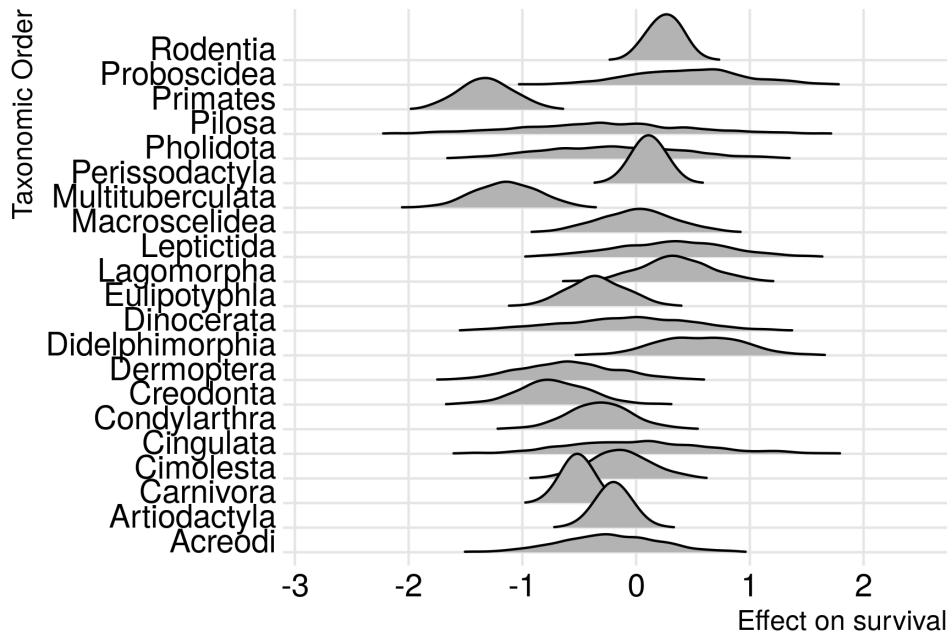

Figure 13

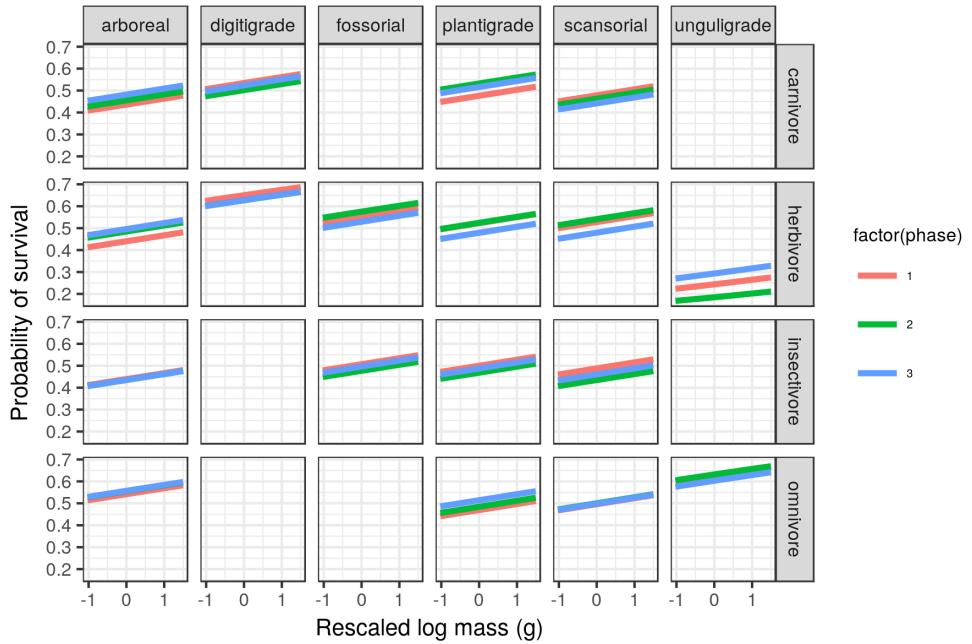

Figure 14: Mean estimate of the effect of species mass on the probability of a species survival for each of the three plant phases. The effect of mass is considered constant over time and that the only aspect of the model that changes with plant phase is the intercept of the relationship between mass and survival. The three plant phases are indicated by the color of the line. Mass has been log-transformed, centered, and rescaled; this means that a mass of 0 corresponds to the mean of log-mass of all observed species and that mass is in standard deviation units. For clarity, only the mean estimates of the effects of mass and plant plant are plotted.

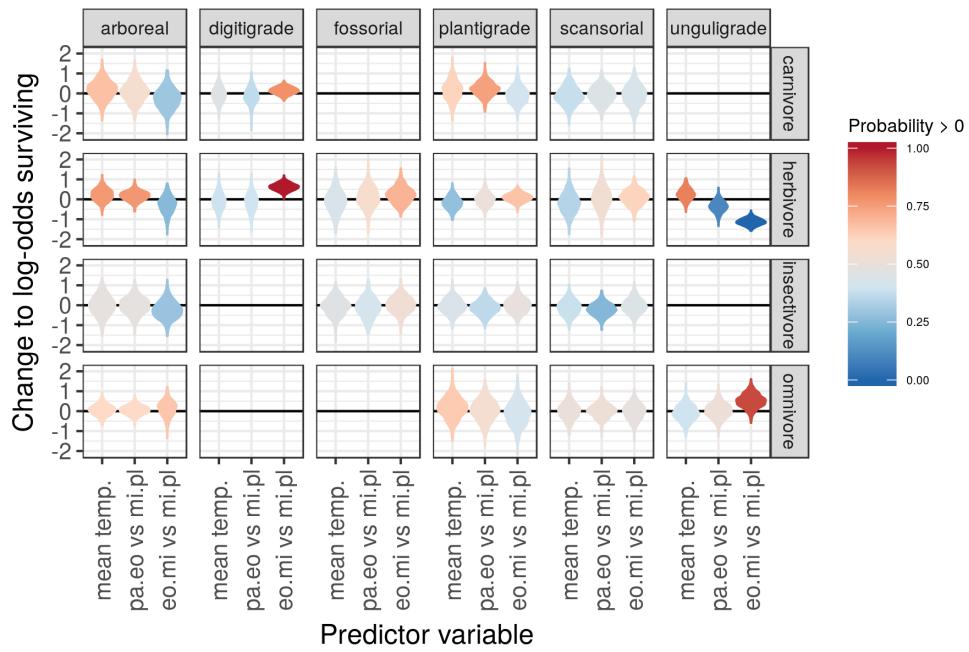

Figure 15: Estimated effects of the group-level covariates describing environmental context on log-odds of species survival. These estimates are from the birth-death model. What is plotted is a violin of the distribution of 1000 samples from the approximate posterior. The effect of plant phase graphed here is calculated as Phase 1 = $\gamma_{phase\ 1}$, Phase 2 = $\gamma_{phase\ 1} + \gamma_{phase\ 2}$, and so on.

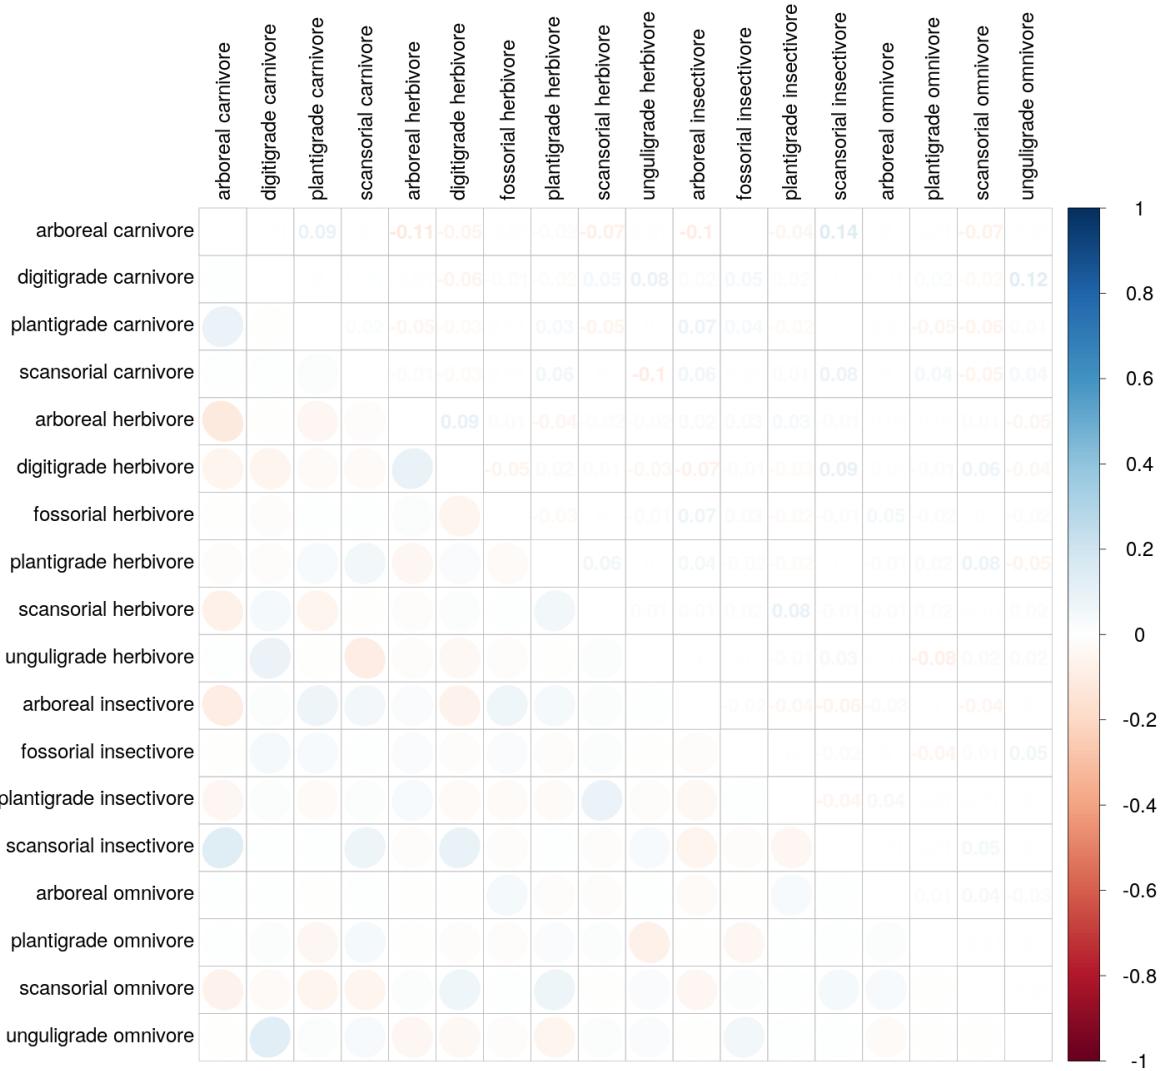

Figure 16: Posterior mean estimates of the correlations in survival probability between the mammal ecotypes. The lower triangle of the matrix is populated with ellipses corresponding to the level of correlation between the two ecotypes, while the upper triangle of the matrix corresponds to the mean estimated correlation between ecotypes. Darker values correspond to a greater magnitude of correlation with blue values corresponding to a positive correlation and red values a negative correlation.

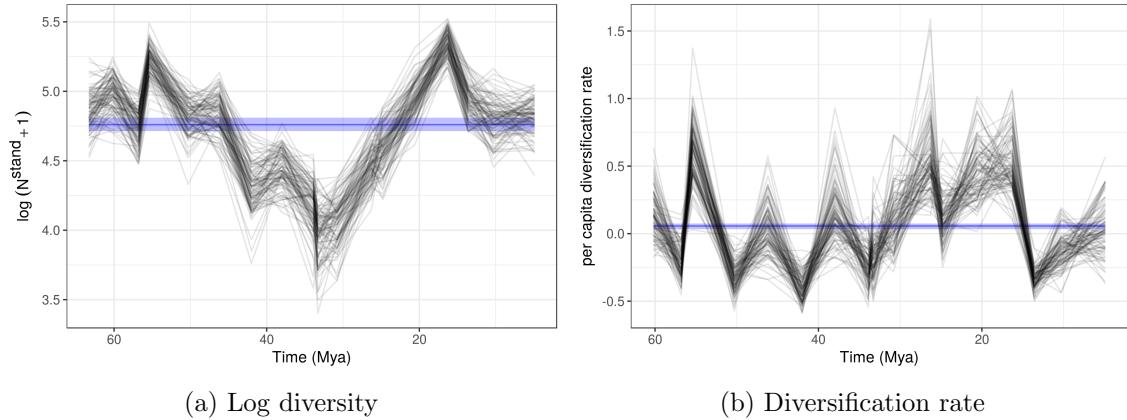

Figure 17: Posterior estimates of the time series of Cenozoic North American mammal diversity and its characteristic macroevolutionary rates; all estimates are from the birth-death model and 100 posterior draws are plotted to indicate the uncertainty in these estimates. The blue horizontal strip corresponds to the 80% credible interval of estimated mean standing diversity, diversification rate, origination rate, and extinction rate respectively; the median estimate is also indicated. What is also plotted is the The dramatic differences between diversity estimates at the first and second time points and the penultimate and last time points in this series are caused by well known edge effects in discrete-time birth-death models caused by $p_{-,t=1}$ and $p_{-,t=T}$ being partially unidentifiable (Royle and Dorazio, 2008); the hierarchical modeling strategy used here helps mitigate these effects but they are still present (Gelman et al., 2013; Royle and Dorazio, 2008). Diversification rate is in units of species gained per species present per time unit (2 My), origination rate is in units of species originating per species present per time unit, and extinction rate is in units of species becoming extinct per species present per time unit.

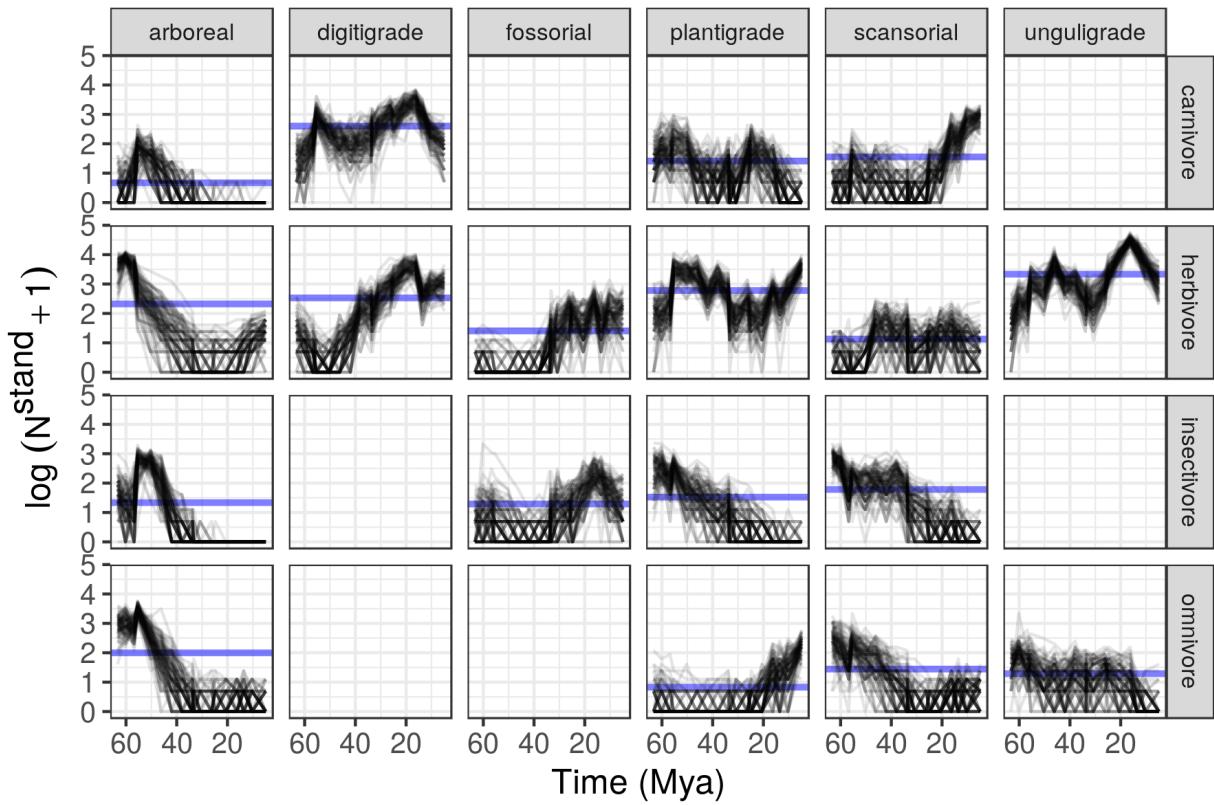

Figure 18: Posterior of standing log-diversity of North American mammals by ecotype for the Cenozoic as estimated from the birth-death model; 100 posterior draws are plotted to indicate the uncertainty in these estimates and what is technically plotted is log of diversity plus 1.

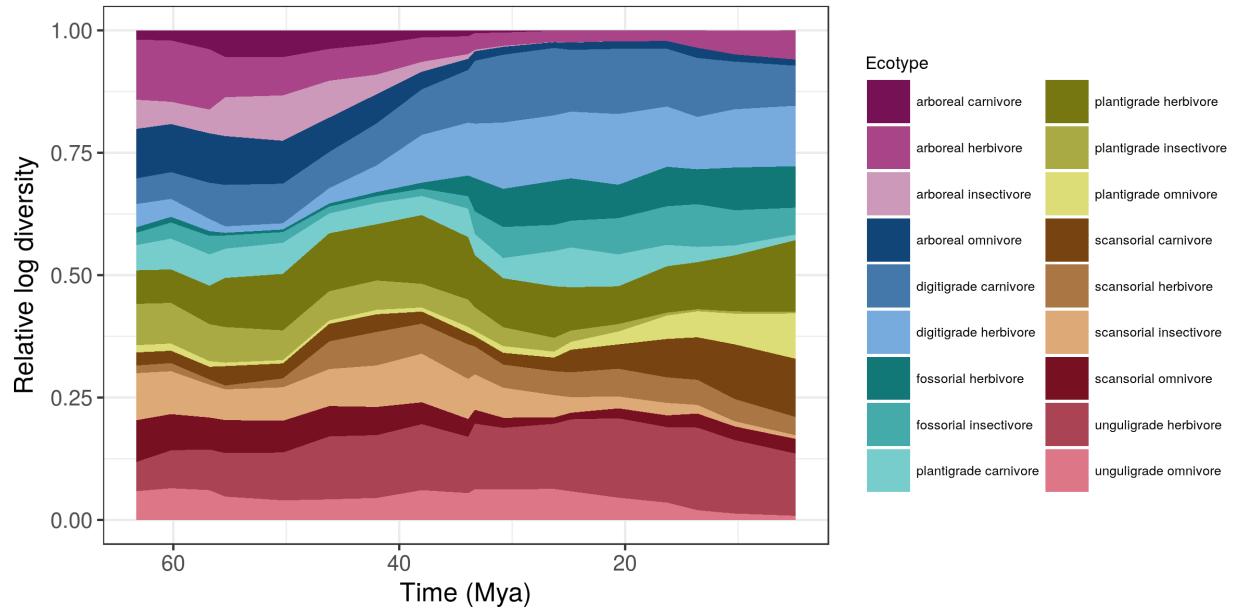

Figure 19: Mean posterior estimate of relative log standing diversity of 18 North American mammal ecotypes for the Cenozoic. These estimates are calculated from 100 posterior estimates of the true occurrence matrix z as estimated from the birth-death model.
